The main radioactive nuclides which can be found in liquid effluents are relatively long lived activation products (60-Co, 55-Fe, 54-Mn, etc.), tritium, fission products (137-Cs, 90-Sr, 106-Ru, etc.), uranium (U), plutonium (Pu), minor actinides isotopes such as americium, curium.... Due to its extremely low radiological impact, aqueous tritium is released in seawaters in Europe. The difficulty in the removal of the radioactivity lies in the complex (when known) composition of the effluent which is often a mixture of complexing, oxidizing or reducing species, suspended solids, organic matters, salts, detergents...with concentrations often higher by orders of magnitude than the targeted radionuclide. It should also be mentioned that the effluent composition may be highly variable, requiring a flexible decontamination process. In recent decades, many studies have been made into the treatment of radioactive wastewaters in a safe method based on four groups of processes: (1) physico-chemical processes, (2) evaporation based processes, (3) biological processes and (4) electrochemical processes. This effort in R&D has drastically increased since the Fukushima disaster as illustrated by the annual cumulated number of citations of the topic radioactive effluent decontamination rising from less than 28 before 2011 to 147 in 2019 (Source: Web of Sciences). Due to their relatively low decontamination efficiency (decontamination factor ranging from 1 to $10^2 - 10^3$) except for evaporation (decontamination factor ranging from 10^4 to 10^6), these processes are effective methods for treating low and intermediate levels waste. Due to its high-energy consumption ($\sim 2.7 \text{ GJ m}^{-3}$ of purified water), evaporation is more attractive for the treatment of small volumes of highly active waste.

It must be pointed out that many methods rely on the combination of two or more of these particular processes.

Physico-chemical processes

Coprecipitation

Among physico-chemical processes, coprecipitation corresponds to the simultaneous precipitation of a normally soluble component with a macro-component from the same solution by the formation of mixed crystals, surface adsorption, occlusion or mechanical entrapment (also referred as inclusion) (see Fig. 1). The precipitates thus formed are of very fine sizes thereby requiring flocculation for faster settlement. The solids are separated and the remaining clear water can be filtered through a sand bed. Flocculation by either cationic or anionic flocculent (see Glossary) has shown improvement in removal of radioactive strontium (Rout et al., 2006). Due to its unique advantages (see Table 1) that makes it extensively used in nuclear industry despite its main drawback, that is the quantity of produced sludge (about 1% in volume of initial liquid volume). Most R&D efforts concentrated on selectivity through chemicals development and on the chemical engineering of the reactions in order to overcome this limitation (Flouret, 2013; Osmanlioglu, 2018). A combination of microfiltration and coprecipitation at a laboratory scale has shown good performances in strontium removal while indicating good potentialities for overcoming the major problems of solid-liquid separation and subsequent sludge concentration in chemical precipitation method (Wu et al., 2014).

From an industrial point of view, coprecipitation is routine for the cesium, strontium, manganese, cobalt, ruthenium and actinides decontamination. As an illustration, after pH adjustment, cesium may be removed by nickel ferrocyanide, strontium by barium sulfate, ruthenium by cobalt sulfide, cobalt by active charcoal.... Other reactants may be used depending on the nature of the effluent. For instance, taking into account the iron component of the waste, the pH adjustment by sodium hydroxide to 9–10.5 induce the coprecipitation of ferric hydroxide along with any radionuclides present in solution and especially actinides. The flowrate are usually high ranging from 100 to 500 m³ d⁻¹ or even more (IAEA, 1992). The decontamination factors obtained at industrial scale are modest (and far below those obtained at laboratory scale) about 100–1000 for cesium, 50–100 for strontium, 6–30 for ruthenium, 1000 for actinides, 100 for manganese. Despite these modest values, chemical precipitation processes appear to be very flexible and quite easy to control. Moreover, chemical precipitation is considered the cheapest process (20–50 times less expensive than evaporation).

Sorption/ion exchange

Solid sorption processes are based on either adsorption or ion exchange into porous matrixes capable to withstand radiation exposure during functioning and to minimize the dosimetry when handling the material. In the context of the Fukushima Daiichi NPP disaster and the necessity to separate most of the 137-cesium (Cs) and 90-strontium (Sr) release in the surroundings waters, a huge number of sorbents have been tested. Among them, much attention has been paid to mineral exchangers (See Glossary) like zeolite (Fang et al., 2017; Sachse et al., 2012), Prussian Blue (PB, ferric hexacyanoferrate) or PB analogs (Metal HexaCyanoFerrates, MHCF see Glossary) nanoparticles (Ishizaki et al., 2013), sodium nonatitanates (Villard et al., 2015), barium titanate (Guevar et al., 2017), ...thanks to their high selectivity and capacity for strontium or cesium. In particular, the outstanding performance of potassium-copper HCF (KCuHCF) towards adsorption of cesium ions has been highlighted as being due to the difference in free energy of the hydrated state between K⁺ and Cs⁺ in aqueous solution and to the vacancy site ratio (Takahashi et al., 2018). Nevertheless,

Reprinted (adapted) with permission from Zhang T, Gregory K, Hammack RW and Vidic RD (2014) Co-precipitation of radium with barium and strontium sulfate and its impact on the fate of radium during treatment of produced water from unconventional gas extraction. *Environmental Science & Technology* 48: 4596–4603, Copyright (2014) American Chemical Society.

Table 1 Pros and cons of the main liquid effluent decontamination techniques.

Method	Advantages	Limitations	Radionuclide	Industrial scale DF
Precipitation	• Not sensitive to salt content • Adapted to large volume • Good decontamination efficiency • Simple • Relatively low cost operation	• Important volume of flocs/sludge • Dewatering system needed for the sludge • Chemical hazards due to the reagents • Efficiency depends on solid-liquid separation step	Cs, Sr, Mn, Co, Ba Ru Actinides	1–100 (10^4 for Cs) 6–30 1000
Ion exchange/adsorption	• Good decontamination efficiency • Adapted to a wide variety of species	• Suspended solid content • Salt content • Absence of nonionic radioactive species • Possible blocking of the bed • Cost of the material • Relatively low sorption capacity and rate • Regeneration and reuse of material	137-Cs 90-Sr 60-Co 65-Zn	1000–10,000 200–2000 10–2000 100
Advanced oxidation process	• Adapted to low contents of organic molecule and suspended matter • Complete oxidation	• Cost of the operation • Pre-mature technique	Cs Zr 60-Co	8–33 (lab scale) 7–22 (lab-scale) 18–43 (lab scale)
Membrane separation	• Reverse Osmosis (RO): removes all ions, high efficiency • Nano-filtration (NF): removes divalent and trivalent ions • Ultra-filtration (UF): separates dissolved salts from particulate and colloidal materials. Good chemical and radiation stability for inorganic membranes • Micro-filtration (MF): complete recovery	• RO/NF/UF: Fouling • organic RO/NF/UF membrane may be sensitive to radiation • MF sensitive to impurities in waste stream	137-Cs 90-Sr 241-Am, Pu, U 58-Co	200–3000 400 1600 500–57,000
Evaporation	• Very good decontamination efficiency and volume reduction provided that the inactive salt content of the stream is relatively low • Relatively high salt content with a wide heterogenous chemical composition	• Detergent content (foaming) • Salt content (precipitation and corrosion) • Organic compounds (risk of explosion) • Expensive (high capital, energy and maintenance costs) • Scaling (heat transfer) • Occupational radiation exposure of workers		10^4 – 10^6
Electrochemical methods	Electrodialysis (ED): • Specific radionuclide removal. • Relatively high salt content • Reasonable useful lifetime Electrodeionization (EDI): • Simple and continuous operation • Chemicals for regeneration completely eliminated • Non pollution, safety and reliability • Complete removal of dissolved inorganic particles • In combination with reverse osmosis pre-treatment, it removes more than 99.9% of ions from the water	• High resistance for the electric current, especially when the feed ionic concentration is low. • Do not remove uncharged impurities • Can form an explosive admixture • An overflow of electric current or concentration polarization can cause the formation of precipitates • Requires purification pretreatment • Its economic viability need to be further assessed	90-Sr, 137-Cs, 129-I, 106-Ru and Hg 137-Cs 90-Sr 60-Co	10 (lab scale) 200–1000 (lab scale) 50–250 (lab scale) 100–200 (lab scale)
Biological sorption	• Cost effective • No chemicals • Good decontamination efficiency (uptake and selectivity)	• Sensitive to impurities in waste stream • requires further dehydration • Dried organic matter to manage in disposal conditions	^{238}U , ^{137}Cs , $^{110\text{m}}\text{Ag}$, ^{60}Co , ^{54}Mn , ^{65}Zn , ^{226}Ra , ^{90}Sr	

most of these materials suffer from relatively slow sorption kinetics or low mechanical strength for practical applications in column operations. These drawbacks have led some research teams to develop new materials based on the grafting of MHCF nanoparticles on mesoporous silica grains (Michel et al., 2017) or monoliths (Grandjean et al., 2020) or on the precipitation of MHCF nanoparticles into the porous network of a geopolymer (See Glossary) (Petlitchaia et al., 2018). The main interest is to benefit not only from the structural properties of these matrixes but also from their compatibility with vitrification or cementation processes. On another hand, PB nanoparticles have been immobilized in cellulose nanofibers and gave satisfactory results in field studies on soil and seawater decontaminations in Fukushima (Vipin et al., 2016). Other promising development concerns graphene oxide (GO), which is an oxidized derivative of graphene. It has been proved that magnetic PB/GO nanocomposites encapsulated in low-cost calcium alginate microbeads exhibit a very high selectivity to Cs and could extract it in trace amounts from natural water or seawater (Yang et al., 2014). However, further studies are required for optimizing the GO by grafting chemically selective functional groups onto the materials surface to increase the sorption capacity of the material (Carey et al., 2018). More recently, a review on PB-carbon nanotubes-graphene nanocomposites concludes on their strong interest in 137-Cs extraction from aqueous media but points out that further studies on the toxicity and regeneration of these materials, on the mode of operation (batch or continuous)....need to be conducted before industrial applications (Rauwel and Rauwel, 2019). In particular, the recovery of these nanopowders has been validated at lab scale via magnetic extraction on attaching Fe₃O₄ nanoparticles to the graphene surfaces (Namvari and Namazi, 2014). The drawback of Fe₃O₄ is that the saturation magnetization is rather low for large-scale applications this potentially leading to some nanomaterial uncaught by the applied magnetic field.

That R&D aim at reducing the overall cost of the decontamination process while keeping a high selectivity towards competing ions, fast sorption kinetics and high sorption capacity. Nanomaterials, with unique physical and chemical properties, such as the nanosize effect, large specific surface area, high adsorption capacity and selectivity have naturally gained an extensive interest for radioactive wastewater decontamination. Nevertheless, a comprehensive review of such nanomaterials based applications has pointed out that their economic viability has not yet been taken into account or even overlooked in recent investigations (Zhang and Liu, 2020).

Novel 3D printing techniques (see Fig. 2) offers new potentialities for the fabrication of hierarchical zeolite monoliths for Cs and Sr removal from nuclear wastewater (Halevi et al., 2020). The 3D-printing process enables control over the dimensions and shapes of the zeolite embedded polymer, and over the degree of porosity and internal structure of the matrix. The monoliths retain the ion exchange properties of the zeolites powders and possess good mechanical stability. Again, it is worth mentioning that these processes have still to be validated at larger scales to assess their techno-economics interest. In particular, the capability of the materials to be easily regenerated for re-use in an environmentally friendly way should be assessed.

From an industrial point of view, ion exchangers based on organic resins have been used since the 1980s in NPP or FCC. The typical volume of the column reactor is between 0.1 and 10 m³ and the DF for 137-Cs and 60-Co were initially low about 15–20 and 4–24 respectively. More recently inorganic commercial exchangers Cs-Treat® (Fortum, Finland, www.fortum.com) based on ferrocyanide claim a DF for cesium usually between 1000 and 10,000 for evaporator concentrates and higher than 8 million for the Fukushima NPP contaminated waters. Last, titanium oxide based products SrTreat® and CoTreat® (Fortum, Finland) are highly selective ion exchangers respectively for strontium (DF higher than 165 million for the NPP contaminated waters when combined with precipitation and usually between 200 and 2000) and cobalt (DF between 10 and 2000).

Membranes

Membrane processes are pore-size dependent filtration processes including microfiltration (MF), ultrafiltration (UF), nanofiltration (NF) membranes and reverse osmosis (RO, see Glossary) with a dense membrane for ions in solution (see Fig. 3). A membrane is a layer of material which serves as a selective barrier for some components allowed passage into a permeate stream, whereas others, such as the radioactive isotopes are retained and accumulated in the retentate stream. Tubular ceramic MF and UF membranes have been used in the field of low or intermediate-level liquid effluent treatment. UF can be used for removal of all substances that are present in radioactive waste in colloidal or suspended form, which cannot be removed, by evaporation or ion exchange. To improve the efficiency of UF and MF, selective sequestering agents, which are often macromolecular ligands (e.g., polyacryl phosphonic, polyethyleneimine and polyacrylic acid), have been used to bind with radioactive ions. For instance copper hexacyanoferrate acts as a surfactant and form micelles with Cs in water, which adsorbs on UF or MF membrane. Ceramic NF membranes can be used to retain multivalent ions (or organic compounds of moderate molecular weight) from monovalent ion present in the solution (Ferreira-Esmi, 2014). It is worth noting that when combined with selective ligands such as resorcinarenes or calixarene, NF can selectively remove 137-Cs (Chitry et al., 2001). Nevertheless, the synthesis of such molecules is costly and increased attention has been given to reverse osmosis (RO) for cesium removal from wastewater at laboratory and pilot-scales (Wang and Zhuang, 2019). Despite the fact that RO membranes are composed of dense organic layers, recent study shows a limited degradation of a semi-industrial RO module under gamma irradiation with promising performances in Cs and Sr retentions (Combernoux et al., 2017). Nevertheless, organic membrane fouling and ageing under irradiation are still questioning the industrial viability of such processes leading to compromised performance and shortened lifespan of the membranes.

In order to overcome the problem of fouling while keeping a radionuclide removal efficiency as high as possible, adsorption or complexation combined with membrane filtration (NF/UF) has been proved to be more effective than membrane filtration used solely (Zakrzewska-Trznadel, 2003). Recently, a submerged membrane (MF) adsorption reactor system has shown its potential reliability for the Cs removal at large scale (Han et al., 2019).

From an industrial point of view, membrane technologies (reverse osmosis alone or in combination with a ultrafiltration or microfiltration pretreatment, ultrafiltration and microfiltration alone) have been used for the treatment of liquid waste originated from NPP or FCC (IAEA, 2004). Examples of DF ranging from 500 to 57,000 are common, in particular with regards to colloidal 58-Co. These technologies have been proved to be industrially viable for processing alpha contaminated waste from fuel reprocessing, for processing separate batches of spent media transfer liquid (sluice water), for reducing the NPP's liquid effluent mixed fission and activation product activity.

Advanced oxidation processes

Advanced oxidation processes (AOP) involves in the two stages of oxidation process. The first stage of oxidation process is the creation of strong oxidants (hydroxyl radicals, $\text{OH}\bullet$) and the second stage is the reaction of these oxidants with organic contaminants in wastewater. Among different available AOP producing hydroxyl radicals, photochemical processes using hydrogen peroxide, H_2O_2 , and ultraviolet radiation (UV-C) and heterogeneous photocatalysis (see Glossary) using titanium dioxide, TiO_2 , and ultraviolet radiations (UV) are the two most popular technologies for the decomposition of low concentration organic waste (see mechanisms on Fig. 4). However, UV-C photo-Fenton AOP (see Glossary) using ferrous ions is more adapted for the decomposition of relatively high concentrations of oxalic acid produced by the decontamination of nuclear power plant (Kim et al., 2019a). For other types of radioactive effluent like those generated by the nuclear fuel treatment, dissolved radionuclides (like 60-cobalt, Co(II) , or uranium, U(VI)) can be complexed by organic molecules (like ethylenediaminetetraacetic acid, EDTA) at trace concentrations. The $\text{OH}\bullet$ produced in situ by $\text{H}_2\text{O}_2/\text{UV-C}$ or TiO_2/UV methods promote the degradation of the organic molecules leading, in the case of dilute U(VI) -EDTA complex, to the reductive deposition of the uranyl ions on the TiO_2 surface (Chen, 1997). In the case of Co(II) -EDTA complex, the degradation of EDTA leads to either the adsorption of cobalt onto TiO_2 particles and/or to the precipitation of cobalt cation Co^{2+} depending on the pH (Rekab et al., 2015). At a lab scale, the obtained DF values were in the range 18–43 for 60-Co. In almost the same conditions, Seshadri and coworkers obtained DF values ranging from 7 to 22 for Sr and from 8 to 33 for Cs (Seshadri et al., 2008).

Fig. 3 Various membrane filtration technologies. In membrane filtration, the use of a pressure difference across the membrane, a transmembrane pressure is an essential driving force for separation. From Nordic Membrane Laboratory website (www.nordicmembrane.com).

It should be noted that the advanced oxidation process is still a pre-mature process and process validation at large scale is definitely needed.

Evaporation

Evaporation is a proven method for the treatment of liquid radioactive waste with nonvolatile radionuclides and salts providing both high decontamination factors and good concentration of salts and radionuclides in bottom concentrate (see Fig. 5). Although it has relatively high operating costs (high-energy consumption), its large volume reduction (of about 100), high decontamination factor (10^4 – 10^6), and the stability in operation make it more suitable than other techniques for processing intermediate- and high-level radioactive waste liquid. However, flowrate are usually lower than those used for other physico-chemical methods. As an illustration mature technologies based on two stages evaporator claim that decontamination factors up to 5×10^7 are achievable for non-volatile radionuclide (see NUKEM website). Another innovative technology has been recently developed and validated at relatively large scale; by continuously controlling the drag/entrainment effect due to the vapor production during evaporation, the process is capable of separating the water molecules from the others. This yields to DF for ^{137}Cs as high as 10^6 at pH 7 and 3.3×10^5 at pH < 7 even in the presence of volatile compounds or salts (see WoW website).

Clean water is removed as vapor leaving behind non-volatile components such as salts and most radionuclides. Nevertheless, the entrainment of radioactive droplets with vapor stream is inevitable, which contaminates the condensate and thus reduces the DF. Much work concentrated on that issue and recently the working principle and operational characteristics of a decontamination tower based on sieve trays for washing the vapor have been published (Deng and Huang, 2017). However, it is worth noting that Westinghouse Electric Company LLC, in the frame of the general design assessment of AP1000 nuclear power plant, claimed that using ion exchange and filters offers a simpler and safer option that will still effectively control discharges of radioactivity due to radiation exposure risks linked to evaporation (Environment Agency, 2011).

Electrochemical processes

Electrochemical processes, in which the electric potential is the driving force, encompass electrodialysis (ED, see Glossary) and electrodeionization (EDI, see Glossary) and have been developed in the late 1950s (see Fig. 6). They are carried on with the use

Fig. 4 Illustration of some of the events taking place in UV/visible light-irradiated semiconductor photocatalysts (like TiO_2) in the presence of ozone and molecular oxygen in aqueous media. Pollutants and intermediates degrade into H_2O and CO_2 . Reprinted from Serpone N, Artemev YM, Ryabchuk VK, Emeline AV and Horikoshi S (2017) Light-driven advanced oxidation processes in the disposal of emerging pharmaceutical contaminants in aqueous media: A brief review. *Current Opinion in Green and Sustainable Chemistry* 6: 18–33, Copyright (2017) with permission from Elsevier.

of ion-exchange membranes, which act as selective barriers. The main advantages of ED lie in the fact that the electrochemical elution eliminates the need for addition of chemicals to elute the targeted radionuclide from the ion exchange resin and very small volumes of the eluting solution can be used in a complete recycle mode in order to minimize the total volume of the radionuclide eluate. DF as high as 10^4 were obtained for the removal of cesium from spent ion exchange resins at the laboratory scale (Bontha et al., 1996). The main drawback ED lies in a phenomenon known as concentration polarization (due to Donnan exclusion) that decreases cell efficiency and lead to a very high-energy consumption especially when dealing with huge volume of low radioactive wastewater. In order to eliminate this disadvantage, EDI has been developed in the 1950s but has suffered from a slow advance likely due to its complex functional kinetics. A comprehensive review (Alvarado and Chen, 2014) points out the primary advantages of EDI that include residue free operation, low process cost and exemplary efficacy in ionic separation and pave the way towards new applications. Basically, the working principles of EDI lie in three simultaneous actions, i.e., (i) exchange of salt ions in the solution with mobile ions in the ion exchange resin; (ii) the continuous transport of ions to the concentrate stream through the ion exchangers and membrane layers; and finally (iii) the continuous regeneration of ion exchangers by hydrogen and hydroxyl ions in situ produced as a result of dissociation of water under an electric field. Furthermore, electrochemical treatment processes can be controlled remotely and automatically, are tunable via system parameters such as operating voltage, and avoid direct exposure to radioactive wastes. Thus, it is no surprise that these electrochemical treatments have rapidly been implemented throughout the world to treat aqueous wastes containing 137-Cs, 60-Co, nitrate wastes resulting from nuclear fuel fabrication plants, and organic wastes such as scintillation cocktails (El-Aziz and Khalifa, 2016). As an illustration EDI has been successfully applied for the purification of primary coolant of a NPP reaching DF values as high as 1000 (Yeon et al., 1999).

As an illustration, the electrically-switched ion exchange is a Cs^+ separation technique where the exchange of Cs^+ ion can be controlled easily by electrode potential. It is capable of overcoming a shortcoming of MHCF (and especially copper MHCF, CuHCF) based processes linked to the fact that small sized CuHCF particles will result in second contamination to water and shorten powdery CuHCF's service life. Moreover, pure CuHCF suffer from low surface area and a poor conductivity thus leading to slow Cs^+ exchange rate and small Cs^+ distribution coefficient. To overcome these limitations a recent process has been developed based on copper hexacyanoferrate/multiwalled carbon nanotube (CuHCF/MWCNT) hybrids. In addition to the remarkable Cs^+ selectivity and removal performance, CuHCF/MWCNT hybrids can be recycled and show a high stability during Cs^+ disposal (Zheng et al., 2017).

An active R&D is still in progress around the world. For instance, a very recent method for the decontamination of nuclear plant cooling water has been developed at MIT based on shock electrodialysis (SED) (Alkhadra et al., 2020). Like ED, SED passes an electric current perpendicular to flow in order to guide ions out of a purified stream of water and into a concentrated brine to be disposed of. However, the separation of fresh and brine does not make use of a physical barrier like a membrane. Instead, the streams are separated by a stable concentration "shock" that arises from passing overlimiting current between the electrodes. This shock is stable in flow and possible only because of the SED device's carefully chosen porous media, which must have pores small enough to prevent the formation of vortices and have enough surface charge to promote the surface conduction of oppositely charged ions. This technique is used to selectively, continuously, and efficiently remove cobalt and cesium from a feed of dissolved lithium, cobalt, cesium, and boric acid commonly found in light-water reactors and in other nuclear processes. In general, the energy

Fig. 5 Principle of an agitated thin film evaporator. From the Concept Process Equipment website (www.conceptprocess.com).

consumed during this process (ranging between 1.76 and 4.8 kW h m⁻³) is low because only charged species are targeted and virtually no energy is expended removing boric acid, the most abundant species in solution.

Although promising that technique still has to be validated at larger scales not only in a technical point of view but also regarding the economics of the whole value chain including the saved cost of disposal or storage.

Biological processes

Bioremediation strategies are gaining significant interest owing to their relative cost effectiveness and eco-friendliness. Various types of microorganisms including fungi, algae, cyanobacteria, and phytoplankton have been reported to retain radionuclides in harsh ionizing environment (McGraw et al., 2018; Chicote et al., 2005). For instance a microalga, *Coccomyxa actinabiotis*, capable of withstanding ionizing radiation doses up to 20,000 Gy, rapidly accumulates most of the metallic radionuclides contained in nuclear effluents including ²³⁸U, ¹³⁷Cs, ^{110m}Ag, ⁶⁰Co, ⁵⁴Mn and ⁶⁵Zn with decontamination rates above 90%. The process feasibility has been demonstrated at real-scale. Once dried, the algae volume was reduced by 90% leading to a volume of radioactive waste at least 100

Fig. 6 Representation of (A) an electrodialysis process and (B) an electrodeionization cell. The spheres represent the ion exchange resin; *AEM*, anionic exchange membrane; *CEM*, cationic ExchangeMembrane. Reprinted from Alvarado L and Chen A (2014) Electrodeionization: Principles, strategies and applications. *Electrochimica Acta* 132: 583–597. <https://doi.org/10.1016/j.electacta.2014.03.165> (web archive link,) with permission from Elsevier.

lower than that of resins (Rivasseau et al., 2013). On another hand, the remarkable ability of the cyanobacterium *G. lithophora* to retain high activities of ^{226}Ra and ^{90}Sr in comparison with other organisms makes it an attractive candidate for bioremediation applications in the decontamination of low-salinity radioactive wastewater streams. Nevertheless, complete development of *G. lithophora*-based $^{90}\text{Sr}/^{226}\text{Ra}$ bioremediation need further studies notably on its tolerance to ionizing radiation and to other metal-loids present in the waste streams (Mehta et al., 2019). Recently, the combination of magnetic separation and bioaccumulation in a micro-alga, *D. armatus*, has been proved to be promising for ^{137}Cs removal from radioactive wastewaters containing competing cations (Kim et al., 2019a, b). Nevertheless, validation at larger scale is still lacking.

The following Table 1 summarizes the main pros and cons of these techniques from the above references and from reference reviews (IAEA, 2001; Abdel Rahman et al., 2011; Rana et al., 2013; Barré et al., 2018).

A case study: The decontamination of cooling waters in Fukushima Daiichi nuclear power plant

A brief history of a disaster

At 3:42 pm, Friday 11 March the first tsunami wave hit the Fukushima No. 1 nuclear plant, followed by a second 8 min later. These submerged and damaged the seawater pumps for both the main condenser circuits and the auxiliary cooling circuits, notably the residual heat removal (RHR) cooling system. They also drowned the diesel generators and inundated the electrical switchgear and batteries, all located in the basements of the turbine buildings thus causing three catastrophic meltdowns of the cores of units 1–3. At 7:03 pm a Nuclear Emergency was declared. Efforts to bring the overheating reactor units of Fukushima Daiichi back under control involved the injection of water directly from the sea, containing a range of substances as well as salt. This water flowed across the molten reactor cores and picked up a range of radionuclides before emerging from the damaged reactor vessels to accumulate in the building basements. The result was an enormous and increasing inventory of polluted and highly radioactive water that represented a major hazard in itself. Unable to prevent the water from leaking out of the reactor vessels, Tokyo Electric Power Company (Tepco) reduced the amounts in the basements by pumping to on-site waste management facilities and then establishing a system to decontaminate the water so that it could be re-injected, using the basements as a part of a closed cooling loop.

The solution, designed to respond to the emergency and support ongoing operations was constructed in record time—two and a half months rather than the usual 3 years. This solution came in the form of the Actiflo®-Rad process, developed in collaboration with AREVA, VEOLIA and the CEA and accepted by TEPCO on April 8, 2011 (Prevost et al., 2012). It relies on a combination of proven nuclear coprecipitation technologies and coagulation, flocculation and sedimentation technologies used for over 20 years in the water treatment industry (see Fig. 7). The saline effluent produced by the upstream oil separation and cesium preadsorption stages is mixed beforehand with differently charged reagents to trap the target radionuclides. This effluent is then transferred into four compartments in series, the first of which is the coagulation tank, where iron chloride (FeCl_3) is added and the pH adjusted. The second compartment is the mixer-contact or where the micro sand is added and the third, called the maturation tank, is where a polymer is added to improve flocculation. The solid precipitate and colloid matter settles in the fourth tank, which contains an inclined plate clarifier (filter) to improve the solid-liquid separation process. The sludge produced is pumped out at the bottom of this last tank. Two stages of this type were set up in series at Fukushima Daiichi, with the only difference between the two stages

Fig. 7 Actiflo-Rad[®] operating principle.

being the absence of the micro sand injection step and the hydrocyclone in the first stage. The process was integrated into an overall system of treatment processes, including an oil separator and pre-treatment process using cesium adsorption upstream and reverse osmosis and an evaporator to desalinate the decontaminated water downstream. After the feasibility tests, a program was conducted to optimize the operating conditions, during which the reagents in the Fukushima seawater were qualified (nickel and potassium hexacyanoferrate to adsorb the cesium, barium chloride to coprecipitate the strontium with barium sulfate) and the optimum contact times defined. The process effectively started on June 17, 2011 and ran until the end of September of the same year. The Actiflo[®] Rad unit reduced the radioactivity of the wastewater by a factor of 10,000 (DF of 10^4 for cesium over the entire period), even with significant salt content (seawater diluted twice) at a flow-rate slightly below the design value of $50 \text{ m}^3 \text{ h}^{-1}$. Between June and September 2011, the system treated 80,000 m^3 of water with a radioactivity of 1 GBq/kg for a total decontamination of 80,000 TBq. About 600 m^3 of waste sludge was produced in total and stored in shielded containers before possible vitrification (Amamoto et al., 2016).

In August 19, 2011 a supplementary and simplified active water retrieve and recovery system (SARRY) plant to remove cesium was installed and commissioned. The system incorporated adsorption towers with ion-exchange resins to grab and immobilize cesium radionuclides (^{137}Cs , ^{134}Cs) present in the water. Over the following months, the system was improved, and a return loop with desalination added so that treated water could be used to cool the reactors. By the end of May 2012, the system had treated 177,000 m^3 of water, and, by storing the treated water in huge tank farms on site, managed to lower the flooding levels in the buildings to below the water table. But with nearly 160,000 m^3 of highly-active water stored in tanks around the site, and the continuing use of some fresh water for the 500 m^3 of daily cooling injection into reactor units 1, 2 and 3, the situation was clearly unsustainable.

Therefore, in March 2013, TEPCO started to operate an Advanced Liquid Processing System (ALPS) to treat all of the contaminated water by removing 62 radionuclides. These are not all of the radionuclides present—researchers have identified more than 1000—but are the ones judged to approach the closest to regulatory maximum levels for seawater, according to Japanese reactor regulations. The cesium is first removed from the contaminated water—reactor-cooling water and ground water flowing in the buildings—using SARRY II plant, from which the freshwater component for further reactor cooling is separated. The remaining wastewater from the RO process is then treated by ALPS. Two notable nuclides that will not be substantially removed by this system are tritium (see *infra*) and carbon-14 but the maximum concentration of this nuclide in the treated water is only 11% of the regulatory standard required by Japanese law (2000 Bq/l) for discharge into the Ocean (see METI website). Water treatment processes in general do not eradicate every last active molecule; they are designed to conform to discharge limits set by the national regulator (see METI website) that vary by country and radionuclide. These guidelines bring radioisotope concentrations post-treatment close to, or below, the limits of detection. TEPCO has chosen Toshiba as the prime contractor for the so-called “multi-nuclide removal system” (ALPS) created by EnergySolutions. The core of the treatment system consists of adsorption stage, in which ion exchange occurs, with extra pretreatment beforehand to remove precipitates and organics. First, a ferric flocculation process that targets ruthenium isotopes; second, a co-precipitation process that removes calcium, magnesium and strontium as carbonates. In both stages, a crossflow ultrafiltration step forces water through a porous ceramic pipe (hole diameter: $0.02 \mu\text{m}$), trapping solids and organics whilst allowing water to pass through. Flocculates, precipitates and organics, which accumulate as sludge, are pumped into 1.9 m

tall by 1.6 m diameter cylindrical radwaste storage containers. In the adsorption stage, water flows through a series of adsorption towers. Because radionuclide concentrations are relatively low, their media are not worth sluicing out; instead, the entire tower is replaced once the resins are spent (on about a monthly basis, or 15 times a year, according to TEPCO).

On the evening of January 24, 2020, the total volume of contaminated water treated by ALPS at the Fukushima Daiichi NPPs surpassed the milestone of 1 million t. As of March 12, 2020, some 1.19 million cubic meters of treated water are stored within 979 tanks on the plant site. The total tank storage capacity will amount to approximately 1.37 million cubic meters by the end of 2020 and all the tanks are expected to be full around the summer of 2022. Therefore, a decision on the disposition path for the stored treated water—after further treatment as needed—should be taken urgently, considering safety aspects. Two options for controlled disposal- vapor release and discharges to the sea- are under examination since both are technically feasible.

Particular case of tritium contaminated water

It has become common practice for nuclear plants around the world to dump into the sea water tainted with tritium, a radioactive isotope of hydrogen that emits very low beta particles and cannot be separated from water under the current purification system, after dilution, based on standards set by each country. There's no hazard posed by external radiation of tritium, which is similar to water and does not secrete into any particular organs in fish or humans through the food chain (ASN, 2019). In the beginning of 2020, a panel of experts advising Japan's government recommended releasing the tritium-tainted water into the ocean after dilution in order to meet the standards set under the law. A simulation of what would happen to the people in Fukushima Prefecture has shown that if all of the approximately 860 trillion Bq of tritium-tainted water were released slowly over 1 year after dilution, the environmental impact would be between 0.052 and 0.62 μSv a year. This dose is significantly less than the one received from natural background radiation, diagnostic X-rays or air travel. For example, in 2015, the La Hague nuclear fuel reprocessing plant in France discharged 13.7 quadrillion Bq of tritium water into the sea.

All possible measures have been exhausted to contain the water, including building an "ice wall" or drilling wells to keep groundwater from entering the reactor buildings, but almost 9 years after the disaster, those measures alone are not enough. It is probably time to put an end to the issue and gain acceptance from the Japanese people for a sea discharge just like at other nuclear plants. Nevertheless any decision to dispose of the waste water into the sea will require intense dialogue and confidence of local fishermen, residents and neighboring countries such as South Korea.

Concluding remarks

Due to the increasingly stringent regulatory frameworks for radioactive waste management, decontamination is a key step for engendering public confidence in the industry. As an illustration, the French group Electricité de France (EDF) which operates the nuclear reactors in France has reduced the radioactivity of its discharges, with the exception of tritium and carbon 14, by a factor of more than 100 over the past 20 years.

To date, conventional techniques such as chemical precipitation, evaporation, adsorption, ion exchange and membrane separation have been industrially applied with their own advantages and limitations. Among them, adsorption is probably the most widely used technique for removing various soluble matters from wastewater. The current R&D focus on novel techniques that take benefit from the combination of the above processes or from new advances in technologies (3D printing, nanomaterials, etc.). The main objective is to maximize the selectivity and capacity while minimizing the duration (optimize sorption kinetics) of the treatment process for limiting both the volume of final waste and the dose for the working on-site staff. For instance, a combination of membrane separation and (co)precipitation or new nanomaterials like carbon based nanocomposites exhibit promising performances. Unfortunately, most of the studies have not been validated at large scale and their economic viability is then questionable. Moreover the majority of the publications does not consider the capability of the final waste (e.g., used (nano) adsorbent and ion exchange material loaded with high-concentration radioactive nuclides) to be recovered, optionally regenerated and finally properly integrated into the waste management system. There is thus a need to develop a specific Life Cycle Assessment of the whole value chain from the radioactive effluent to the final disposal. This systemic approach must take into account issues as human exposure to radiation (direct exposure of on-site working staff and indirect exposure due to the release of improperly treated radioactive wastewater), safety (classical hazards like aerosols, chemicals, nanoparticles, etc.), environmental impact and costs (treatment, packaging, transportation and disposal). Such a multi-criteria approach should enable the design of novel decontamination techniques capable to be industrially implemented.

In a context where nuclear energy should play a growing role in the future for seriously tackling the challenges of the climate change, the quest for such processes is thus likely to be pursued in the next decades.

Glossary

Cold-cap A cold melt surface that can minimize volatilization of radionuclides.

Skull A protective coating on the internal surface of a crucible.

Waste product Refers to a conditioned waste stream that requires further processing prior to long-term storage and disposal.

Waste streams Refers to an individual waste type.

Wasteform Refers to a conditioned waste stream that would be suitable for long-term storage and disposal.

ILW conditioning and performance

Intermediate level wastes (ILW) typically contain long-lived radionuclides at a concentration, and with a half-life, that will require long-term disposal in a facility which provides more containment than near-surface disposal (e.g. in an engineered repository tens to hundreds of meters below ground). The definition of ILW wastes varies from country to country, however, the International Atomic Energy Agency (IAEA) defines ILW as material with a higher activity than low level waste (LLW), but that does not require active cooling in storage conditions ([International Atomic Energy Agency, 2009](#)). The typical lower limits of activity are 4 kBq g^{-1} for long-lived alphas, and tens of kBq g^{-1} for long-lived beta/gammas ([International Atomic Energy Agency, 2009](#); [Radioactive Waste Management Limited, 2017](#)). Most notably, the United States does not have an ILW category, however, under IAEA classification many wastes defined under US law as either high level, transuranic or low level may be recognized as ILW in other jurisdictions, and, as such, may be cited as examples throughout this article. Intermediate level wastes contain a diverse range of chemistries, physical properties and radionuclide inventories, which has resulted in a wide application of immobilization and encapsulation technologies to these wastes over many decades of successful treatment.

The performance of ILW wasteforms, especially in disposal conditions are highly dependent on the encapsulation or immobilization matrix and the engineered barrier systems to be employed within a repository (geological, or near-surface). The long-term performance of ILW wasteforms are not necessarily primary factors in choice of immobilization matrix in the same manner as highly active wastes (containing high concentrations of long-lived radionuclides). Many of the shorter/medium-lived isotopes predominant in ILWs will have substantially decayed prior to the eventual breakdown of geological repository barriers, reducing the risk of potential long-term radiotoxicity. ILW wasteforms are typically packed within an outer container (e.g. steel drums or concrete boxes), which will degrade before substantial interaction between wasteform and groundwater can occur. Post-closure repository conditions, whether it is a cementitious, clay, or salt backfill, will dominate near-field conditions long into the future, either limiting water ingress, or conditioning groundwater to limit radionuclide mobility. These repository conditions are key to limiting radionuclide mobility for ILW, whereas HLW are expected to remain radiotoxic long after the degradation of repository engineered barriers, with a corresponding greater emphasis on their long-term durability.

Here, we detail some of the most common, operational and emerging treatment technologies for ILW treatment, ranging from conventional cementation and bituminization, through to a wide range of thermal treatment technologies, including a brief indication of their longer-term performance within an engineered waste repository.

Cementation

Cementation of nuclear wastes typically refers to the physical encapsulation and solidification of wastes using an inorganic binder which is capable of setting at ambient temperatures. Most often this refers to the usage of a blended Portland cement grout, either

mixed waste to be immobilized or poured around solid materials (e.g. compacted drums), then left to set, typically within a stainless steel drum or box.

Portland cements

Portland cement (PC) is the most widely used and manufactured cement worldwide, with widespread usage within the construction industry and a relatively well understood chemistry. It is produced via the calcination of clays (alumino-silicates) and limestone (CaCO_3) at $\sim 1450^\circ\text{C}$ before being ground into a fine clinker, with the addition of gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) or anhydrite (CaSO_4) as setting regulators. To this powder, limestone or other minor components may be added according to national or wider legislation (e.g. European standard EN 197-1). Although many different varieties of Portland cement exist, a typical Portland cement clinker consists principally of alite (Ca_3SiO_5 , 50–70%), belite (Ca_2SiO_4 , 15–30%), ferrite ($\text{Ca}_4(\text{Al,Fe})_2\text{O}_7$, 5–15%) and aluminate ($\text{Ca}_3\text{Al}_2\text{O}_6$, 5–10%). Minor oxides such as Na_2O , K_2O and MgO usual constitute less than 5% of the clinker (Taylor, 1997; Atkins and Glasser, 1992).

Portland cement gains strength primarily through hydration of alite and belite (with belite reacting more slowly than alite), but also ferrite and aluminate phases. These clinker solids are unstable in the presence of water, and within seconds of mixing produce a highly alkaline solution which accelerates dissolution-precipitation reactions. Alite and belite react to form a poorly crystalline calcium silicate phase (typically denoted as 'C-S-H') which is the principal strength giving phase within Portland cements, with excess calcium precipitating as $\text{Ca}(\text{OH})_2$. The chemical composition of this 'C-S-H' phase is somewhat flexible, accommodating a Ca/Si ratio from ~ 0.7 – 1.7 , giving it a unique pH buffering capability and ensuring alkaline conditions prevail within the cement pore solution (along with $\text{Ca}(\text{OH})_2$). The aluminate phase is highly reactive, rapidly forming hydrated calcium aluminate phases which give early stiffening of the paste (prior to C-S-H precipitation), but is controlled by the supply of sulfate into solution from gypsum and anhydrite. In the presence of gypsum, ettringite is formed ($\text{Ca}_6\text{Al}_2(\text{SO}_4)_3(\text{OH})_{12} \cdot 26\text{H}_2\text{O}$), typically converting to monosulfate over time ($\text{Ca}_4\text{Al}_2\text{SO}_4(\text{OH})_{12} \cdot 6\text{H}_2\text{O}$) as more aluminate reacts. Hydration of ferrite typically follows the same pathways as aluminate, forming an iron substituted ettringite, although more slowly.

Various supplementary materials can be combined with Portland cement, finding routine usage in both construction and the nuclear industry. These can have cementitious properties, affecting the hydration of Portland cement in beneficial ways such as altering the chemistry of C-S-H, increasing fluidity, lowering the heat of hydration, and reducing porosity. Industrial sources typically consist of blast furnace slag, fly ash and silica fume, but also include burnt shales. Natural materials include pozzolans such as volcanic tuffs and natural zeolites, along with those which have undergone additional processing including rice husk ash and calcined clays. Most of these materials have a high proportion of glassy aluminosilicates (illustrated in Fig. 1), with varying levels of CaO, MgO, SiO_2 and Fe_2O_3 , which can readily react within the highly alkaline, Ca rich pore solution of Portland cements (Taylor, 1997; Lothenbach et al., 2011). The use of these supplementary cementitious materials often decreases the Ca/Si ratio within the C-S-H, and results in Al substitution, forming C-(A)-S-H gels, while materials richer in MgO (such as some slags) can precipitate hydrotalcite ($\text{Mg}_6\text{Al}_2\text{CO}_3(\text{OH})_{16} \cdot 4\text{H}_2\text{O}$).

Fig. 1 $\text{CaO-Al}_2\text{O}_3\text{-SiO}_2$ ternary diagram of cementitious materials, represented as oxides in weight %. From Lothenbach B, Scrivener K and Hooton, RD (2011) Supplementary cementitious materials. *Cement and Concrete Research* 41(12): 1244–1256.

Cementation with Portland cements has been favored as a flexible treatment option for ILW wastes worldwide due to the following (Fenton and Holland, 2001; Sharp et al., 2003; International Atomic Energy Agency, 2017; Crossland and Vines, 2001; International Atomic Energy Agency, 2004):

- Ability to process at ambient temperatures, avoiding volatile emissions
- Intrinsic fire resistance due to being an inorganic binder
- Able to solidify liquid or sludge wastes
- High radiation stability, with dense material also providing radiation shielding
- Formed from relatively low cost commercially available materials
- Chemically tolerant of many waste streams
- High pH pore solution limits mobility of many radionuclides
- Limited porosity allows some gas migration, but provides a diffusion barrier against radionuclide release

These waste grouts almost always utilize partial or high level replacement (routinely up to 90%) of Portland cement with blast furnace slag (BFS or GGBS) or fly ash (sometimes known as ‘pulverized fuel ash’, PFA or FA for coal power plants). These blended Portland cements offer a lower heat of hydration along with reduced cracking and porosity, while maintaining adequate fluid characteristics during mixing (Atkins and Glasser, 1992; Glasser, 1992) and forming familiar cement phases (Fig. 2 depicts the fine microstructure of a PC-BFS blend (Taylor et al., 2010)). In the United Kingdom, PFA blends are used as capping grouts (i.e. to infill around supercompacted material) due to the increased fluidity from these blends, while BFS blends are typically used as the main grout for a wide range of wastes.

Cementation is a flexible process, in which liquid or solid wastes are mixed with cement either outside drums (allowing pours into several drums), or in-drum via a lost paddle mixing process. After setting, wasteforms may be capped with a layer of inert grout before package sealing. In-drum grouting is another implementation, where solid items are placed then in-filled with grout, with optional vibration to improve infilling and eliminate voids. Annular grouting is also performed, where multiple compacted drums are stacked inside a larger drum, then surrounded by inactive grout; this has been applied in supercompaction facilities treating low density wastes (Crossland and Vines, 2001; International Atomic Energy Agency, 2004).

Though typically encapsulating, rather than chemically incorporating wastes (unlike vitrification within a glassy matrix), the chemistry of the cement phases formed and the pore solution help to limit radionuclide mobility. The high pH environment (initial pH > 12) will cause many of the transition, alkaline earth, lanthanide and actinide elements to form poorly soluble precipitates—elements which often account for the majority of ILW radionuclide inventory (Crossland and Vines, 2001). Certain elements are not as strongly retained within cement, particularly monovalent cations (e.g. $^{137}\text{Cs}^+$) and anionic species other than inorganic carbonates (e.g. $^{36}\text{Cl}^-$, $^{129}\text{I}^-$, $^{99}\text{TcO}_4^-$). However, Cs^+ mobility is hindered by sorption as a charge compensating ion within a C-(A-)S-H phase,

Fig. 2 TEM micrograph of C-S-H in a PC-BFS blend containing 75% slag sample, cured for 20 years. From Taylor R, Richardson IG and Brydson RMD (2010) Composition and microstructure of 20-year-old ordinary Portland cement–ground granulated blast-furnace slag blends containing 0 to 100% slag, *Cement and Concrete Research* 40(7): 971–983.

anionic species exhibit some limited sorption to ettringite, partially replacing SO_4^{2-} , and a lower porosity wasteform, which will necessarily lengthen the time taken for migration of poorly interacting species out of the product (Glasser, 2001).

Although Portland cements are a flexible encapsulation matrix, certain wastes might not be fully compatible with conventional PC blends. Oils are poorly encapsulated, organic materials may degrade over time (resulting in non-aqueous phase liquids, or potentially cracking cement through volume changes), and salts may deleteriously affect cement setting characteristics (either accelerating, or retarding setting) (International Atomic Energy Agency, 2017). Reactive metals such as uranium, aluminum and magnesium alloys can corrode in the high pH or free water conditions of a cement matrix, potentially resulting in expansive corrosion products forming which can crack cements (Sharp et al., 2003). Though not precluding these wastes from cementation, consideration is required for predicting wasteform evolution and maximum waste loadings.

Potential issues with Portland cement blend usage in the future include the significant volume increase from cementitious solidification, as well as any longer-term deleterious waste-cement interactions (reactive metals, organic degradation, etc.). An emerging concern is also that of ensuring continuity of cement supply. The nuclear industry is a very minor consumer of cementitious powders, with industrial production geared towards satisfying demand from construction industries. Changing national and supra-national standards over decades (especially with a move towards lowering embodied CO_2 content of cements) can result in difficulty of supplying cementitious powders to specific particle size, reactivity and chemistries preferred for usage at fixed ILW and LLW cementation plants (which may operate over several decades). This is a particular issue in the United Kingdom due to the projected closure of all coal fired power plants by 2025 (which supply PFA) and concerns over the long-term future of steelmaking (supplying BFS/GGBS), with numerous changes to BFS supplier over the past 20 years as blast furnaces are shuttered (Angus et al., 2010).

Alkali activated cements

Alkali Activated Cements (AACs) consist of a powdered precursor, typically with a high content of glassy $\text{SiO}_2\text{-Al}_2\text{O}_3$ (with or without CaO/MgO) which is 'activated' via addition of an alkaline solution, often sodium (or potassium) hydroxide or silicate, though carbonate and sulfate activation have been studied. Suitable materials available in industrial quantities include blast furnace slag, fly ash, and metakaolin (MK), though natural pozzolans can also be used. The main distinction between the various alkali activated cements is the calcium content, with BFS cements containing high contents of calcium, PFA available as calcium containing or relatively calcium free, and MK which are calcium free (Provis and Bernal, 2014).

Activation of calcium rich precursors results in a set cement product with characteristics and a mineral assemblage similar to that of blended Portland cements. The main binder is a poorly crystalline C-(A-)S-H gel, often with hydrotalcite formed if the precursor contains MgO . These cements have found interest for a variety of reasons. Reduced sulfur present in slags can bring a negative redox potential, which may limit the mobility of certain redox sensitive radionuclides (e.g. ^{99}Tc), and both final pH and porosity can be altered depending on activator and slag chemistry, opening up possibilities for tailored wasteforms and reduced leaching. Resistance to corrosive environments is claimed to be higher, with some studies finding reduced Cs leaching, postulated to be due to lower Ca/Si ration within the binder phase, along with Al substitution in the C-S-H gel (as C-(A-)S-H) helping to retain Cs (Shi and Fernández-Jiménez, 2006).

Activation of low calcium precursors results in a very different product, dominated by a highly cross-linked aluminosilicate gel often defined as a 'N-A-S-H' gel (or the potassium equivalent), which lacks long-range ordering. These are typically called geopolymers, and are usually produced through the mixing of metakaolin (a partially dehydrated kaolinite clay) with sodium (or potassium) silicate solutions at varying ratios, molarity and water contents to target specific Na_2O (or K_2O)- $\text{SiO}_2\text{-Al}_2\text{O}_3\text{-H}_2\text{O}$ contents for optimum performance (Provis and Bernal, 2014). Sodium hydroxide cured FA geopolymers are possible, though typically require steam curing due to slow strength development, and as such are not widely utilized.

As geopolymer cements are largely calcium free, and do not rely on a traditional clinker dissolution step, they are potentially more tolerant towards certain waste streams than Portland cements. High salt bearing wastes, which typically affect PC hydration can be targeted, as can oil bearing wastes which can partially saponify within the highly alkaline pore solution, allowing better entrainment within the cement matrix (Cantarel et al., 2015). Formulations can be adjusted to encourage the precipitation of zeolites, which can more readily retain problematic radionuclides such as Cs (Arbel Haddad et al., 2017). They have also been studied for encapsulation of reactive metals, using NaF (which would normally precipitate as CaF_2 in PC systems) to passivate Mg-Zr alloys, which would allow encapsulation of metallic wastes from UNGG reactors in France (Rooses et al., 2013). Commercial geopolymers (e.g. SIAL[®]) have also found useful application in immobilization of radioactive sludges, ion exchange materials and coolant fluid in Slovakia and Czechia, with wide scale usage since 2003 (Lichvar et al., 2013).

Though not relying on a calcium-based chemistry, these geopolymers maintain a high pH and therefore retain certain benefits of traditional PC-blended systems. These systems have not, however, found widespread adoption in industrial waste cementation. Issues include being a 'two part' system rather than the 'one part' PC powder and water traditionally used. Geopolymer formulations also require careful balancing between reactivity, targeted end-composition, and rheology. The latter, rheology, can be an issue due to the very high surface area of metakaolin and non-standard rheology, along with the water content of wastes affecting calculations. High calcium alkali activated materials such as blast furnace slag can be more easily formulated, have a rheology closer to PC blends, and a chemistry which is more familiar. Unfortunately, these are still calcium based, and are incompatible with many of the same waste streams as PC blends, and also suffer from similar concerns over security of supply into the future, resulting in only limited uptake for bulk waste cementation.

Magnesium phosphate cements

A very different class of cementitious material, which have gained traction for waste immobilization, are magnesium phosphate cements (MPCs). Originally developed for use as refractory cements for application in steel plants, these were popularized as rapid repair cements, finding usage on roads, runways and sidewalks. These cements are in essence a controlled acid-base reaction between magnesium oxide and an acidic phosphate (Walling and Provis, 2016), enabling rapid setting, and the ability to set at sub-zero temperatures. The reaction between MgO with H_3PO_4 is rapid and strongly exothermic, however by calcining MgO until 'dead burnt', this begins to sinter and reduce reactivity, while usage of weakly acidic granular phosphates (e.g. $\text{NH}_4\text{H}_2\text{PO}_4$) further reduce reactivity. This controlled reaction (Eq. 1) results in the formation of a crystalline phosphate mineral called Struvite, which forms a coherent cementitious mass.

A slight modification on these, using KH_2PO_4 instead of ammonium phosphate as a starting material produces analogous Struvite-K (Eq. 2). Magnesium phosphate cements based on Struvite-K were first developed for radioactive waste encapsulation at Argonne National Laboratory, as cements tolerant of ash and salt bearing wastes. Also known as chemically bonded phosphate ceramics (CBPCs), and commercially as 'Ceramicrete', these cements have been trialed both in Russia and the United States for nuclear waste cementation of Pu contaminated ashes, Tc bearing wastes (using reducing agents to reduce Tc to less soluble Tc(IV)), salt wastes at Mayak (Russia) and liquid wastes from the Hanford site (United States) (Wagh, 2004).

Struvite-K is favored for nuclear applications due to slower reaction times (resulting in slower heat evolution) and no evolution of gaseous ammonia during setting. They are typically blended with a high proportion of diluent, either PFA or BFS, which further reduce the heat output that is especially important as wastes will be solidified in massed drums. Borates are used as highly effective setting retarders, typically applied as borax ($\text{Na}_2\text{B}_4\text{O}_7 \cdot 10\text{H}_2\text{O}$) or boric acid (H_3BO_3) at several weight percentage (wt %) to further extend setting and suppress the maximum heat evolution (Walling and Provis, 2016).

The internal pore solution of MPCs is close to neutral, which makes these cement systems of interest for encapsulation of waste containing reactive metals, such as aluminum fuel cladding, which forms a passive layer at circumneutral pH. The relatively high proportion of crystal bound water within Struvite-K has also drawn research to applying these cements to other reactive metals (uranium and magnesium alloys), which can react in free water. If water is mostly crystal bound after mixing, rather than available in pore solutions this has the potential to reduce corrosion in wasteforms. These cements may also be more tolerant of salt rich wastes, and there is also some interest in structural substitution of K^+ within Struvite-K with Cs^+ , more effectively binding cesium rich waste streams (Leng et al., 2020; Walling and Provis, 2016).

Calcium sulfoaluminate cements

Calcium sulfoaluminate (CSA) cements have garnered some interest for application to radioactive waste immobilization. These cements are made from firing calcium sulfate, limestone and bauxite together (analogous to PC production, though at a slightly lower temperature of $\sim 1250^\circ\text{C}$) to form ye'elimite ($\text{Ca}_4\text{Al}_6\text{SO}_{16}$) and other minor clinker phases. This is typically ground with ~ 15 – 25% gypsum to form a packaged powdered product. Hydration with water results in the formation of ettringite, monosulfate and aluminum hydroxide via Eq. (3)–(4) (Winnefeld and Lothenbach, 2010):

Ettringite formation (and thus water requirements) are highly dependent on the content of gypsum added, resulting in a modifiable cement product. In comparison to Portland cements, the internal pH of a CSA cements are lower, typically ~ 10.5 – 11 , due to the lack of free $\text{Ca}(\text{OH})_2$. Though ettringite has been proposed as a useful immobilization phase for anionic radionuclides, CSA cements are mainly of interest for the encapsulation of reactive metals. Similarly to magnesium phosphate cements, these have been trialed for metallic aluminum encapsulation, including usage in Savannah River p-reactor decommissioning (Hayes and Godfrey, 2007; Stefanko et al., 2010). Ettringite, as the principal hydrate phase in CSAs incorporates a significant bound water concentration, and are expected to result in less free water within the pores, CSA cements may therefore also be suitable for metallic Mg and U wastes.

Performance

Cements utilized for waste cementation are usually high pH materials with a more porous nature than glasses, ceramics or polymers. This results in a greater degree of water ingress and gas migration than other ILW wasteforms. As such, the mechanical integrity of cementitious wasteforms is not as critically important, with radionuclide release largely dominated by chemical conditioning of wastes and waste-wasteform interactions (Glasser, 2001).

Cements are constantly evolving, albeit slowly, with cementitious reactions continuing years after waste emplacement due to unhydrated clinker, unreacted slag or fly ash, and the influence of groundwater or waste materials. These reactions may continue

strengthening the cements, but can also be associated with undesirable reactions. The degradation of cemented wasteforms from groundwater is a key factor in their longevity, with the ingress of chlorides and sulfates deleteriously affecting the cement binder through the formation of expansive mineral phases, such as ettringite or thaumasite, resulting in cracking ([Radioactive Waste Management Limited, 2016](#)). Groundwater migration will also slowly affect the local pH, through removal of free alkali in pore solutions, then dissolution of $\text{Ca}(\text{OH})_2$, followed by slow decalcification of the C-S-H/C-A-S-H gel. Carbonation can also lower the cement pH, either from atmospheric CO_2 during storage, or dissolved carbonates in groundwater. Understanding these changes are key to wasteform longevity, as under alkaline conditions many radionuclides are likely to exist as poorly soluble oxides or hydroxides, severely limiting their migration (reducing conditions from slags also assist with radionuclide retention). The presence of different mineral phases within the cement also support radionuclide sorption, though some radionuclides (notably Cs) do not form insoluble hydroxides, and are only weakly sorbed by C-S-H/C-A-S-H ([Glasser, 2001](#); [Glasser, 1992](#); [Crossland and Vines, 2001](#)).

As these are inorganic materials, radiolytic degradation is much less of a concern, though this may cause reactions with organic material (such as chloride release from PVC degradation), and can cause H_2 formation from pore water radiolysis ([Radioactive Waste Management Limited, 2016](#)). Microbial degradation is also unlikely to affect cements deleteriously, with the high pH also reducing microbial activity. Of greater impact on wasteform integrity are specific waste interactions within the cements, in particular the expansive reaction products of ion exchange resins or encapsulated reactive metal corrosion which may induce cracking, accompanied by gas production. Other wastes such as flocs, slurries or raffinates may slowly react with the cements and may result in shrinking (or expansive reactions) and cracking, making it important to understanding waste-cement interactions.

For the alternative cements, such as geopolymers and MKPCs, their long term performance is less well understood. Geopolymers are highly alkaline, with the N-A-S-H gel binder expected to provide substantial pH buffering, and consequently reduced radionuclide mobility. Alkali activated slag cements will perform closely to blended PC/BFS cements, but likely with a higher pH and more reducing environment. MKPCs are near-neutral, with performance likely to rest upon the slow dissolution of the main hydrated magnesium phosphate phase, and the behavior of encapsulated wastes. Specific dissolution rates, or durability of cements are very difficult to determine, varying greatly by waste, type of cement, and proposed engineered barrier systems within a geological repository. Some countries, such as the United Kingdom, place reduced weight on cement wasteform durability, as proposed cementitious backfills and the predicted long durability of steel containers in these conditions are liable to keep these conditioned until much of the radioactivity has decayed ([Radioactive Waste Management Limited, 2016](#)).

Bitumen

Bitumen is a thermoplastic, which is solid or semi-solid at room temperature, comprising a complex mixture of high molecular weight hydrocarbons. Though bitumens occur naturally, industrial applications utilize material from asphaltic crude oil distillation. In waste immobilization, these can be further categorized into 'straight run' bitumen obtained by direct distillation of crude oils, 'blown' bitumen, in which air is blown through bitumen at 200–250 °C, and 'emulsified' bitumen which has various soaps or emulsifiers added to vary the properties ([Valcke et al., 2014](#); [International Atomic Energy Agency, 1993](#)).

The bituminization process for nuclear wastes is usually either via continuous extrusion, or thin film evaporation. Continuous extrusion comprises pouring both heated bitumen and waste into a heated rotating screw extruder, which intermixes both materials, extruding a homogeneous product out into a drum. During this process, water and low molecular weight hydrocarbons are evaporated and removed, with the final product left to cool after. Thin film evaporation utilizes a cylindrical vessel with rotating blades which pass very close to the heated wall. Waste and heated bitumen are added at the top, and are both spread and thoroughly intermixed on the walls by the blades, with gravity pulling this mixture towards a drum underneath the vessel. Countercurrent hot air removes water and volatile organics, again resulting in a product which is left to cool after ([International Atomic Energy Agency, 1993](#)).

The appeal of bituminization is that of a highly flexible process with good compatibility for organic materials, and ability to achieve high waste loadings with a low permeability, and lower leach rates than cementation. It is a relatively simple process with low operating costs, finding usage with immobilization of chemical precipitates (especially from fuel reprocessing) and low heat/low alpha decay wastes. This process found notable usage in Belgium for high salt content wastes from fuel reprocessing, along with Sweden and Finland for immobilization of ion-exchange wastes, France, and more minor usage in Japan, Germany and Switzerland amongst others ([Valcke et al., 2014](#); [International Atomic Energy Agency, 2017](#); [International Atomic Energy Agency, 1993](#)).

Bituminization does have some severe drawbacks that have limited its widespread adoption worldwide. Though suitable for high salt content wastes (Eurobitum wastes in Belgium are ~60 wt % blown bitumen and ~40 wt % salts, mainly as NaNO_3 and CaSO_4), swelling of these wasteforms from osmotic pressures can cause considerable volume expansion and are of concern in final disposal conditions (with research also ongoing into the effect of salt release on the clay backfill) ([Valcke et al., 2014](#); [Mariën et al., 2013](#)). Waste materials may require pre-treatment as dehydrating salts, strong oxidizers (e.g. sodium nitrate), and tributyl phosphate can be fire hazards; indeed several fires have been documented at bituminization plants, due to poor understanding of wastes prior to immobilization ([International Atomic Energy Agency, 2017](#)). Bitumen products also offer poor radiation shielding due to low density, requiring extra shielding during processing/transport, and are particularly affected by radiolytic degradation.

This radiolysis and associated radio-oxidation can result in gas release (particularly H_2), swelling and embrittlement of the wasteform over time (International Atomic Energy Agency, 1993; Valcke et al., 2014).

The degradation of bituminous wastes is complex and is governed predominantly by type of bitumen used, exposure to radiation, and type and quantity of wastes encapsulated. In general, bitumen is very resistant to chemical action, with a low water diffusion and radionuclide release if carefully produced. Over time bitumen will age, predominantly via oxidation. This can result in a slow hardening, embrittlement and cracking of the wasteform, which may provide pathways for enhanced water ingress and radionuclide release (Valcke et al., 2014). Oxidation typically begins at the surface, slowly migrating inwards and forming lightweight organic degradation products, though only affecting a small proportion of the wasteform as oxygen diffusion is low (Pettersson and Elert, 2001). Wasteform contact with water can result in bitumen swelling, along with leaching of soluble organic molecules from oxidation or radiolytic degradation processes (Valcke et al., 2014). If particularly hygroscopic wastes are encapsulated (e.g. salts or dried organic resins) at high waste loadings, then water uptake and osmotic pressures can result in considerable swelling, exerting pressure on waste containers, resulting in fissures and potential radionuclide release (Hendrix et al., 2016). Radiolysis from encapsulated wastes can result in further swelling and breakdown via gas evolution, along with embrittlement, especially when exposed radiation doses exceeding $> 10^7$ Gy (International Atomic Energy Agency, 1993). The radiolytic gases evolved are predominantly H_2 , with minor contributions from CO, CO_2 and low weight organics (Radioactive Waste Management Limited, 2015; Pettersson and Elert, 2001). The associated fire hazard from hydrogen evolution, and potential organic release within a repository has generated questions about the ultimate disposal route for these wastes.

Microbial degradation of bitumen wasteforms is possible, however, it is reported to be low and unlikely to affect wasteform durability, especially under anoxic conditions likely to be prevalent in geological repositories (Radioactive Waste Management Limited, 2015). Ultimately, the rate of radionuclide leaching is highly dependent on their solubility, with reported values in the range of 10^{-4} to 10^{-1} $g\ m^{-2}\ d^{-1}$ for actinide and rare earth metals, and 5×10^{-2} to $50\ g\ m^{-2}\ d^{-1}$ for alkali and alkaline earth metals (International Atomic Energy Agency, 1993).

Polymers

Polymers have been utilized for the immobilization of problematic wastes that are unsuitable for other routine immobilization methods. The most notable advantage of polymer encapsulation is tolerance of a wide range of waste chemistries at high waste loadings, including organic materials, reactive metals, and high salt wastes, which may preclude efficient cementation (US Department of Energy—Office of Environmental Management, 1999; Radioactive Waste Management Limited, 2015). Polymers used for immobilization are organic synthetic plastic materials typically broadly classified as either thermoplastic or thermosetting (International Atomic Energy Agency, 2002; Radioactive Waste Management Limited, 2016).

Thermoplastics are materials which soften upon heating, and are generally supplied in a solid form. Their chemistry is largely unchanged by heating, allowing re-molding and incorporation of wastes before solidifying upon cooling. The most common thermoplastic studied for ILW encapsulation is polyethylene (consisting of repeating $-CH_2-$ units) and bitumen (discussed in section 'Bitumen'). Polyethylene (PE) processing is undertaken using an extrusion processes with wastes and PE added into a feed hopper, heated (low-density polyethylene (LDPE) becomes fluid $\sim 85^\circ C$) and intermixed through an extrusion screw before entering a drum which is left to cool (Radioactive Waste Management Limited, 2015). This polymer is readily available and less flammable than bitumen. Some water is driven off during the heated extrusion process, though wastes with high water contents require a drying step before addition. As no chemical reactions are required to produce a solid product, this polymer is extremely tolerant of wastes, highly chemical resistant and solidified products exhibit low leach rates (Radioactive Waste Management Limited, 2016).

Thermosetting polymers are liquid at room temperature, and require either the application of heat or various curing/hardening agents to initiate cross-linking polymerization and for a hardened product. Common thermosetting polymers for immobilization include: epoxy resins, polyester resins and urea formaldehyde (International Atomic Energy Agency, 2002).

Solidified epoxy products are typically made from the combination of an epoxy resin with a hardener. A wide range of epoxies are manufactured, with varying physical properties, allowing tailored solutions to varied waste streams. However, the correct ratio of hardener to epoxy is required to control reactions, meaning some epoxies are sensitive to water content and pH of wastes. The most common epoxy resin is based upon the reaction of epichlorohydrin with bisphenol A in the presence of sodium hydroxide, forming bisphenol A diglycidyl ether (BADGE; Fig. 3) (Radioactive Waste Management Limited, 2015). The oxirane group in the BADGE reacts with varying curing agents (amines, anhydrides, phenols and thiols), cross-linking to form a hardened product. Very high strengths can be achieved, though this often results in brittle products. These epoxies exhibit very good leach resistance along with low flammability but are attacked by strong acids. France has successfully used epoxy resins to immobilize ion exchange resins

Fig. 3 Bisphenol A diglycidyl ether (BADGE).

since 1996 using the MERCURE process, entailing a lost-paddle mixing procedure once waste, epoxy and hardener have been added (Radioactive Waste Management Limited, 2015).

Polyester resins have found usage, due to high flash points and ability to incorporate water (with an emulsifier), including for ILW in the United Kingdom (Trawsfynydd NPP ion-exchange immobilization) using vinyl ester styrene (Radioactive Waste Management Limited, 2015). Produced via polymerization of linear polyester with a cross-linking initiator, these polymers can achieve high compressive strengths and are in general very chemically resistant (International Atomic Energy Agency, 2002; Radioactive Waste Management Limited, 2016). Urea formaldehyde is not commonly utilized for waste immobilization. Though these are low cost and low temperature while curing, a particular problem is the formation of acidic water (which remains liquid within the waste-form after setting) that can corrode conventional steel containers. Compressive strengths are low (Radioactive Waste Management Limited, 2015), as is their tolerance to radiation (International Atomic Energy Agency, 2002).

Though useful for certain problematic wastes, the drawbacks of polymer encapsulation include their relatively low radiation resistance compared to cementation or vitrification, along with increased cost compared to cementation. Radiolysis can generate hydrogen gas (depending on the polymer), and substantially affect physical properties, including embrittlement and cracking—which may be of concern in a final repository environment (Radioactive Waste Management Limited, 2015).

Polymer stability and degradation largely occurs as a function of the specific polymer utilized. Many of the less suitable polymer types and formulations have been excluded through extensive testing prior to wide-scale waste encapsulation operations, resulting in wasteforms fabricated with stable polymers. In general, engineered polymers degrade and release radionuclides via exposure to high temperature, extensive radiation, and waste-wasteform interactions. Wasteform degradation can lead to reduced compressive or tensile strength (or embrittlement), the formation of non-aqueous phase degradation products, and gas formation (Radioactive Waste Management Limited, 2016). Polymers are extensively resistant to chemical attack (especially PE), and exhibit radiation tolerance up to 10^6 Gy. One notable exception is urea-formaldehyde resins, in which doses $> 10^5$ Gy result in severe damage. Radiolysis of polymers can result in gas formation, the composition being dependent on the polymer (predominantly CO_2 in polyester, H_2 for epoxy and PE) (Radioactive Waste Management Limited, 2015). The presence of high waste loadings with hygroscopic materials (e.g. dried ion exchange resins) can result in deleterious expansion, although the extent of these effects depend on the plasticity of the polymers, with more ductile materials like LDPE being more tolerant of expansive forces (Arnold et al., 1985). Overall leaching rates for radionuclides from polymer wasteforms are considered low in the short term, however, as wastes are encapsulated rather than chemically conditioned, once leaching begins this can provide pathways for enhance leaching, with mobility ultimately dominated by geological repository engineered barriers.

Wet oxidation

Wet oxidation is a low temperature aqueous oxidative process that utilizes hydrogen peroxide coupled with a catalyst (typically iron salts) to produce hydroxyl and hydroperoxyl radicals (as shown in Eq. 5–6) (Babuponnusami and Muthukumar, 2014; Bokare and Choi, 2014). These radicals readily attack organic bonds, with the ultimate aim of degrading organic materials to CO_2 and H_2O leaving a much smaller volume of sludge containing radionuclides within an aqueous solution. This technique is not currently applied to any wastes on an industrial scale, but there have been numerous pilot plants and mobile rigs developed over the past 30 years. These largely focused on degradation of spent ion exchange resins, but also decontamination solutions (containing organic complexants like EDTA and citric acid) and waste reprocessing solvents.

A typical wet oxidation setup for ILW treatment consists of a glass reaction vessel, to which waste (e.g. spent ion exchange resins) and a catalyst are added, heated to ~ 90 – 100°C and slowly dosed with hydrogen peroxide over the course of hours (typically 2–8 h). During this process the resins slowly decompose, first to linear soluble lower molecular weight products and then to CO_2 and H_2O . Resin decomposition releases functional groups (e.g. sulfates and ammonia species), requiring the solution pH to be monitored and maintained at $\text{pH} \sim 2$ – 3 for optimum reactivity (especially for iron catalysts). Decomposition leaves radionuclides within an aqueous solution, which can be neutralized by precipitating many as poorly soluble hydroxides; the resulting sludges may be suitable for cementation (Walling et al., 2021b).

Decomposition of spent ion exchange resins with wet oxidation occurs below 100°C , limiting the risk of volatile element release (e.g. cesium volatilization). This allows for less complex off-gas systems (via retention of decomposition acids within the processing solution and lower radionuclide volatilization), enabling waste volume reduction and allowing degradation of organic complexants (which may preclude acceptance to waste repositories). Trials using pilot plants have been undertaken in the United Kingdom, Europe and the United States, using both iron and copper catalysts, though full implementation of this technology for waste treatment has not occurred (Walling et al., 2021b; Charman and Twissel, 1999). The output wastes generated from wet oxidation are highly unlikely to be directly disposed, and as such may undergo secondary conditioning to form cementitious, glassy or ceramic wasteforms.

Thermal treatment

Thermal treatment embraces a broad range of approaches that include the application of pre-treatment technologies (which convert liquid or solid wastes (e.g. soft organics) into lower volume solids for further treatment), and final-treatment technologies, which produce wasteforms suitable for long-term storage or disposal in a national repository with no further processing required. Thermal treatment is suitable for a wide range of ILW waste streams including organic and inorganic liquids, organic and inorganic solids and metallic wastes. Thermal treatment often converts waste into an integral part of the wasteform, as opposed to cementation where wastes are physically encapsulated (resulting in increased volume). The general advantages of thermal treatment include (but are not limited to) waste volume minimization via the destruction of organics, removal of water, thermal degradation and oxidation of wastes. Thermally treated wasteforms are considered to be more stable with a higher aqueous durability (lower leachability) and radiation tolerance than encapsulated wastes and may be vitreous (glass), glass-ceramic, or ceramic materials, with the phase assemblage controlled by the waste and additive compositions.

A common challenge associated with thermal treatment technologies is the need for off-gas systems to capture and retain radioactivity through a range of functions, such as; off-gas combustion, gas cooling to precipitate particulates and filtration (e.g. filter ash), wet-scrubbing and HEPA filters prior to the emission of the purified off-gas within local regulatory limits. Therefore, thermal treatment is inherently a more complex process, with associated cost implications, when compared to cementation, that also requires the development of suitable process and formulation envelopes to maximize waste loading while controlling criticality and volatility risks. Nevertheless, the production of passively safe products of minimized waste volume, compared to encapsulation technologies, delivers overall lifetime cost savings, arising from downstream storage and disposal, as well as reduced hazard. In this section, thermal treatment technologies for ILW conditioning will be discussed with a range of technological maturity from industrial application to demonstration scale to laboratory scale.

Pre-treatment technologies

Calcination

Calcination of nuclear wastes is a common process for level liquid wastes generated from nuclear fuel reprocessing operations, with the United Kingdom and France utilizing calcination as part of a two-stage calcination-vitrification thermal treatment process for high level liquid wastes, though with the technology applicable to ILW. Typically these exist as spray (350–550 °C), fluidized-bed (500–600 °C) and rotary kiln (500–600 °C) calciners ([International Atomic Energy Agency, 2007](#)). Calcination provides high efficacy volume reduction, elimination of water, salt decomposition, and formation of a stable oxidized waste product ([International Atomic Energy Agency, 2007](#)). The calcination product is a fine powder with concentrated activity that is easily dispersible, and consequently requires further processing.

Incineration

High temperature incineration (1000–1500 °C) promotes the complete combustion of solid and liquid organic wastes in an oxygen rich environment, with the waste products being a solid residue (ash) and an off-gas. Commonly used for the treatment of solid ILW and some ILW, wastes can be solid or liquids (organic, aqueous) but the technology is intolerant to high concentrations of non-combustibles, metallic wastes and plastics ([International Atomic Energy Agency, 2007](#)). An incinerator plant is often composed of primary combustion chamber (and secondary chambers for off-gas oxidation), a boiler to cool the off-gas, off-gas filtration and radiological purification and wet scrubbing prior to discharge ([International Atomic Energy Agency, 2007](#)). Incinerators are a proven technology with worldwide usage for both nuclear and non-nuclear applications including: Austria, Belgium, Canada, France, Germany, India, Japan, Netherlands, Russian Federation, Slovakia, Spain, Sweden, United Kingdom, Ukraine and United States ([International Atomic Energy Agency, 2007](#)). The advantage of incineration in waste management include: it is a proven technology with a high volume reduction, high throughput, and flexible to varying waste streams. The incineration product is a stable oxidized ash that requires additional conditioning, e.g. vitrification, super compaction, or cementation depending upon the activity and waste classification.

Pyrolysis

Pyrolysis is flameless thermal treatment technology that operates upon a dry distillation process where wastes are exposed to external heating in the absence of air/O₂ (inert atmosphere) to promote the fracture of organic compounds (gasification), typically into methane, ethane, benzene, toluene and a carbon-rich char. The product gases undergo off-gas treatment to yield a calorific off-gas, which is subsequently fully combusted and purified ([International Atomic Energy Agency, 2007](#)). The relatively low temperature (500–600 °C) ensures that volatile radioelements are retained with the solid output wastes (e.g. tars and char). Pyrolysis results in a significant waste volume decrease that can be further improved by removal of carbon from the carbon-rich tar. This can be achieved by steam reformation (Eq. 7; not discussed further) or incineration (oxidized) to yield atmospheric carbon (CO₂)

Pyrolysis is deemed a suitable technology for all waste types such as liquids (high in Na, Al, nitrates, nitrites, nitric acid, hydroxides and sulfates), oils, organic solvent, sludges, plastics, cellulose and soils with the exception of inorganic liquids and inorganic ion exchange resins (IERS). There are several examples of pyrolysis plants used for the treatment of ILWs including: Germany

(pebble pyrolysis with $\text{Ca}(\text{OH})_2$ for spent IERs and spent reprocessing solvents); France (IRIS plant, 55% plastics, 35% latex/rubber and 10% cellulose, which is pyrolysed at 550 °C followed by subsequent incineration at 900 °C; O_2 -rich); and in the United States (THOR® process by Studsvik) (International Atomic Energy Agency, 2007). The latter uses additives in the reactor (fluidized-bed) to support the formation of insoluble aluminosilicate minerals (mineralization), which are considered suitable for disposal in high integrity containers (International Atomic Energy Agency, 2007). While in other systems, the final product is typically a granular material that may require further processing (similar to calcination/incineration) to yield a monolith waste product suitable for disposal.

Thermal gasification

An alternative to pyrolysis is thermal gasification (reducing atmosphere) that targets the incomplete combustion of wastes to yield a calorific off-gas, which is subsequently fully combusted and purified. This technology is under development for the treatment of both LLWs and ILWs rich in organic matter (e.g. organic ion exchange resins; IERs), for which cementation of the raw wastes may not be fully suitable (Vehmas et al., 2020).

The VTT thermal gasification design includes a thermal fluidized-bed reactor (bubbling or circulating fluidized-bed reactors) operating at approximately 900 °C, followed by subsequent gas purification processes for gasified wastes; CO , CO_2 , H_2 , CH_4 , O_2 (Nieminen et al., 2020a). Filter dust and bottom-ash (fluidized-bed material; Al_2O_3 and inorganic particles) removed from the reactor constitute the output solid waste. A recent demonstration trial successfully converted Cs-exchanged IER into filter dust, with the solid output wastes equivalent to 1 wt % of the original waste stream (Nieminen et al., 2020b). The solid wastes require additional processing, which is proposed to be accomplished using cementation technology, and more recently geopolymerization (Nieminen et al., 2020a,b; Vehmas et al., 2020). The advantages of thermal gasification include high waste minimization, high conversion of carbon, capture of volatile radionuclides in the filter ash, lower processing temperature and compact design, however, complex off-gas systems are required.

Final treatment technologies

Induction melters

Induction melters use external heating to provide induction heating to a corrosion-resistant metallic reactor vessel (e.g. Inconel alloy crucible) that will contain the waste and glass forming additives, with the resulting product typically a homogenous glass. Induction melters are primarily used in the thermal treatment of HLWs, however, if deemed economically viable, this technology could be applied to a wide range of ILWs, and in particular wastes with a high refractory content.

An example of induction melter is the Atelier de Vitrification (AVM) of La Hague process facility and the Waste Vitrification Plant (WVP; United Kingdom) for the thermal treatment of liquid high level waste (HLW) generated from fuel reprocessing operations (International Atomic Energy Agency, 2007). The UK design is based upon a two-stage process, where the liquid waste is first dried via calcination (600–840 °C) and gravity-fed into the melter at a controlled rate (25 kg h^{-1}) alongside the glass-frit until the melt achieves 1050 °C. The molten glass (waste loading 25–32 wt %) is poured in 200 kg batches into stainless steel canisters (Harrison, 2014), and cooled slowly (annealed). The resulting waste packages are deemed suitable for the long-term storage and disposal.

An alternative system is a Cold Crucible induction Melter (since retrofitted in the La Hague plant (Naline et al., 2010)) where the addition of external crucible cooling leads to the formation of a protective ‘skull’, which essentially provides a protective coating on the internal surface of the crucible, owing to a thermal gradient between the crucible and the molten material (also referred to as the ‘melt pool’). This design allows for processing at higher temperatures (for refractory wastes) and/or more corrosive wastes (Hyatt and James, 2013; International Atomic Energy Agency, 2007). Further alternatives include the in-can vitrification system, which is under inactive commissioning by CEA for processing incineration wastes (e.g. PVC, cotton) and simulant alpha-contaminated effluents, with the can (Inconel alloy) renewed after each cycle (Nieminen et al., 2020b) however, the system can only handle small quantities of organics and metallic waste.

Joule heated ceramic melters

Joule heated ceramic melters (JHCMS) use resistive heating which is directly introduced into the waste/melt by passing an electric current between submerged electrodes in a refractory lined reaction vessel, with a melt formed from glass formers at temperatures reaching ~1150 °C (Goel et al., 2019; Matlack et al., 2010). The waste (in the form of a slurry or calcine) and additional glass formers are introduced during the melt from above, lowering surface melt temperatures (‘cold-cap’) which helps reduce volatilization of certain radionuclides (e.g. ^{137}Cs , ^{99}Tc). The thermal transfer within the melt can be improved through use of bubblers and/or mechanically stirring to actively mix, substantially improving throughput times (Matlack et al., 2010). Final homogeneous glass products are poured into suitable canisters for long-term storage and disposal.

JHCM is a popular choice for the thermal treatment of nuclear wastes with existing plants (or plants under construction) in the United States, Germany, Belgium, Japan with applicability to a wide range of ILW waste streams including sludges, salt rich wastes, and ion exchange materials (both organic and inorganic) (Goel et al., 2019; Matlack et al., 2010; Hyatt and James, 2013). The main technical challenge arises from noble elements, which can accumulate in the melter and impact pouring capabilities (Radioactive Waste Management Limited, 2017; Goel et al., 2019).

In-container vitrification (ICV)

Joule-heated In-container vitrification (ICV) uses resistive heating applied by sacrificial electrodes (typically graphite) with a starter path to initiate melting, due to the low conductivity of waste/glass former. Once initiated, melt conductivity increases, facilitating convective mixing to form a melt pool containing the pre-loaded waste and glass formers. ICV utilizes a refractory lined steel container, which the container forms part of the overall waste package, with no melt pouring required (Fig. 4). The key advantage of ICV technology is its applicability for highly heterogeneous waste streams, including larger complex objects (canisters, sea disposal crates, compacted drums), metallic wastes, along with high processing temperature (up to 1800 °C) (Hyatt and James, 2013; Radioactive Waste Management Limited, 2017). Wastes can either be fully pre-charged into the vitrification container, or partially charged with additional feeding while melting to accommodate volume reduction (Radioactive Waste Management Limited, 2017). The final wasteform may be homogenous or a heterogeneous combination of glass, ceramic and metallic phases (Hyatt and James, 2013).

In-container vitrification has been investigated or utilized for numerous wastes including depleted uranium contaminated soils, metallic sodium wastes, chlorinated organics, and the destruction of asbestos (Walling et al., 2021a). Kurion (now a subsidiary of Veolia Nuclear Solutions) developed the GeoMelt® ICV technology, which ranges in application from full-scale operations to demonstration trials for the vitrification of nuclear wastes. In the United Kingdom, ICV technology targeted plutonium contaminated materials (PCM) and co-mixed Magnox sludge and clinoptilolite/sand wastes with large scale successful demonstrations (Hyatt and James, 2013; Witwer et al., 2010; Nieminen et al., 2020b). In 2018, large scale trials were performed using GeoMelt® technology in the United States for processing metallic sodium contaminated waste from the Fermi 1 reactor, yielding 16 glass waste products, which have since been accepted for disposal at the NNSS (Nevada National Security Site; United States) (Garrett et al., 2020).

Plasma heating

Plasma heating is generated by creating an electric discharge between electrodes, with the electric arc forming a plasma (ionized carrier gas). A plasma torch is designed with concentrically-arranged tubes that are water-cooled and contain a flowing process gas supply, all housed in high-grade refractory liner that can withstand the extremely high temperatures generated. There are two categories of plasma melting systems: non-transferred and transferred. In transferred-torches, the energy is transferred directly from the anode via electric discharge to the molten pool (e.g. slag), which serves as the cathode (International Atomic Energy Agency, 2007). This process is considered more energy efficient than non-transferred torches, where two electrodes, separated by a gas injection chamber, create an electrical arc that ionizes the gas (plasma). The typical plasma temperature for non-transferred torches is 5000 °C, which is lower than transferred-torches but still capable of inducing a melt within the waste material (International Atomic Energy Agency, 2007).

The use of very high temperature is key to the success of plasma facilities, as this enables a wide range of wastes to be treated from organic to inorganic materials, and liquids to solids provided they can be fed into the system, which yields a stable slag/glass waste product. A plasma plant typically consists of four key constituents: waste feeder (batch or continuous), plasma chamber (refractory lined or cold crucible), off-gas system and slag collection system (International Atomic Energy Agency, 2007; Deckers, 2020; Hyatt and James, 2013).

Fig. 4 GeoMelt® technology used in UK ILW demonstrations. Nieminen M, Olin M, Laatikainen-Luntama J, et al. (2020b) Thermal treatment for radioactive waste minimisation, EPJ Nuclear Sciences & Technology, 6: 25.

There are two examples of full-scale plasma plant facilities for the immobilization of nuclear wastes, these are the ZWILAG plasma facility in Switzerland which has operated since 2004 (International Atomic Energy Agency, 2007) and the Kozloduy plasma melting facility (PMF) in Bulgaria operational since 2018 (Deckers, 2020). The ZWILAG plasma facility operates using a transferred-plasma torch capable of reaching plasma flame temperatures of 5000 °C, which equates to a melt temperature of 1200–1500 °C (Heep, 2007). Batch processing sees single 200 L drums containing untreated waste being introduced to the plasma chamber via a horizontal drum feeder, typically totaling 300–400 drums per cycle (Heep, 2007). During processing, the crucible is rotated to utilize centrifugal forces, which prevents the molten slag from nearing the pour port (located at the bottom of the crucible). To enable pour into a slag mold, the crucible rotation is slowed to a suitable speed. Gasified organic wastes are directed through an afterburner (including heat recovery) and off-gas system (International Atomic Energy Agency, 2007; Heep, 2007). Plasma heating is suitable for a wide range of wastes with only minimal pre-treatment (e.g. waste shredding if needed) however, complex off-gas systems are required to process the combusted organic material, volatilities and particulates generated (Hyatt and James, 2013; International Atomic Energy Agency, 2007).

Dual heating vitrification (SHIVA)

The SHIVA (Système Hybride d'Incineration Vitrification Avance) process developed by CEA (Commissariat à l'Énergie Atomique et aux Énergies Alternatives) utilizes dual simultaneous heating (plasma and induction) to achieve the incineration-vitrification of radioactive wastes. The SHIVA technology consists of a water-cooled stainless steel reactor vessel with twin plasma transfer torches (graphite electrodes) located within the reactor chamber and a flat inductor at the bottom (Lemont et al., 2008; Nieminen et al., 2020b). Glass frit is pre-filled into the reaction crucible and heated to form molten glass. During waste processing the plasma torches are sustained with a mix of argon and oxygen (10 L min⁻¹), in contrast to argon-only flow during the start-up phase, which induces an oxidizing atmosphere suitable for the incineration (gasification) of organic wastes. Waste is directly introduced to the plasma zone using a hopper feeder and worm screw with a typical feed rate between 1 and 10 kg h⁻¹ (Lemont et al., 2008; Nieminen et al., 2020b). The gasified wastes are fully oxidized in the plasma chamber, which requires a simpler off-gas system than other thermal treatment technologies (Nieminen et al., 2020b). Once the melt process is complete, the molten glass is drained to yield a homogenous vitrified product, namely an aluminoborosilicate glass.

The SHIVA process is suited to the treatment of organic and inorganic ion exchange materials, in either liquid or solid form, but is incompatible with metallic wastes (Nieminen et al., 2020b; Fournier and Rousset, 2020). The specific advantages include ability to continually feed waste during melting, a cold-crucible design to reduce corrosion, and a compact design which allows operation within hot cells for ILW and HLW (Lemont et al., 2008).

Hot isostatic pressing

Hot isostatic pressing (HIPing) is an alternative advanced thermal treatment process that involves the simultaneous application of induction heating and pressure (typically using Ar(g) as the pressurizing medium) to a hermetically sealed HIP canister (e.g. stainless steel). The processing temperature can be up to 1400 °C with isostatic pressure in the range of 10–200 MPa. The waste streams deemed suitable for HIPing include ILW inorganic wastes, ranging from sludges (e.g. Magnox sludge), spent inorganic ion exchange resins, Idaho calcine and sludges, fissile materials, wastes from medical isotope production to plutonium contaminated materials; however, organic materials are unsuitable. Higher activity wastes are being considered for this technology including potentially immobilization of the UK inventory of civil separated plutonium, which will target a single phase ceramic wasteform (Stewart et al., 2009; Heath et al., 2018; Hyatt, 2020; Radioactive Waste Management Limited, 2017). The advantages of HIPing compared to other technologies include; batch-to-batch processing provides improved inventory accountancy and critically control, lower processing temperature, minimal secondary wastes (fewer off-gas requirements) and high waste loadings (up to 100%) (Stewart et al., 2009).

For HIPing, a certain degree of pre-conditioning is required to prepare the hermetically sealed HIP canister, which can include low temperature calcination (to retain volatile radioelements but drive off water) and waste homogenization (mixing with additives) prior to can filling (Stewart et al., 2009; Heath et al., 2018). During the HIP process, the canister undergoes deformation due to the elevated temperature reactions (e.g. melt or solid-state reaction) and pressure imposed upon the system, which results in consolidation and densification of the waste than can range from a glass, glass-ceramic or ceramic depending on the waste composition and chosen additives, as demonstrated in Fig. 5. One limitation of HIPing is the lack of industrial scale pilot plants to validate the efficacy of for nuclear immobilization; however, the Australian Nuclear Science and Technology Organisation (ANSTO) are currently commissioning a HIP for the immobilization of ⁹⁹Mo/^{99m}Tc bearing wastes arising from medical isotope production (Gregg et al., 2020), while in the United Kingdom, proof of concept radiological HIPing on the laboratory scale is underway (Gardner et al., 2020).

Performance of wasteforms from thermal treatment of ILW

The thermal treatment of ILW may produce either homogenous or heterogeneous glasses and glass-ceramic wasteforms, owing to the complex nature of waste compositions which may be combined in co-mixed waste treatment (e.g. in-can vitrification). It is generally accepted that glasses, ceramics and glass-ceramics have higher chemical durability and thus, higher performance than non-thermal conditioned wastes (e.g. cementation). In ILW glass and glass-ceramic wasteforms, the waste often provides a portion of the fundamental wasteform composition (e.g. clinoptilolite can act as a glass former, as a source of Al and Si, and is fully incorporated within the chemical structure). This is in contrast to cementation, where the waste is physically encapsulated and retains the

Fig. 5 Example photographs of a stainless steel HIP canister before (A) and after HIPing (B) including sectioned HIPed canisters demonstrating simulant Magnox sludge vitrification in a borosilicate glass matrix with uranium (U_3O_8) contents at 0 wt % (C), 7 wt % (D) and 44 wt % (E).

original waste characteristics, which often includes soluble and/or highly mobile species. Natural analogues of glasses and ceramics, dated from thousands to millions of years, provide much needed confidence in the long-term durability and integrity of these materials, including withstanding natural disposal conditions and weathering.

The performance of glass and glass-ceramic wasteforms relates to the chemical durability (i.e. leachability) and radiation tolerance. In geological repository conditions, wasteform dissolution will only occur upon failure of the wasteform container/overpack (typically stainless steel), allowing groundwater ingress. Due to this delay, a significant decrease in radioactivity associated with short lived radionuclides in intermediate level wastes will inherently reduce the risk to the biosphere resulting from radionuclide migration.

Glass dissolution (typically silicate based glasses for ILW) proceeds in three key stages. Stage 1 (also referred to as initial or forward rate), is defined by inter-diffusion and ion-exchange processes. Following a rate-drop, Stage 2 (characterized by a residual rate) occurs, and is defined by hydrolysis of the glass network. This leads to elemental release and alteration of the glass surface via the formation of an amorphous gel-layer and/or the precipitation of secondary crystalline phases, namely phyllosilicates and zeolites in saturated conditions (Mann et al., 2019). The impact of secondary phases is often complex. Gel-layers, rich in Si (but can form as single element-rich bands) are often thought to be passivating and protect the glass surface from further dissolution, while phyllosilicates and zeolites may stimulate progression to Stage 3 (rate resumption), which promotes accelerated elemental release and dissolution rates (Mann et al., 2019).

The rate of glass dissolution is highly dependent on the pH, in particular the solubility of Si (the main glass former), which is reported to increase by two to three orders of magnitude from near-neutral to pH 12 (Radioactive Waste Management Limited, 2016). This solubility trend is also affected by the temperature, where higher temperatures lead to enhanced dissolution rates over a wider pH range. In post-closure repository conditions, the predominant mechanism for radionuclide release from ILW glass wasteforms will arise from contact with groundwater and will be controlled by the near-field environment, temperature and redox conditions. If a high pH (e.g. cementitious, $\text{Ca}(\text{OH})_2$ rich) backfill is utilized in a repository, this may promote Stage 3 (rate resumption) leading to higher dissolution rates (Mann et al., 2019), whereas, a lower-pH backfill (e.g. Boom clay) and low water transport rates will maintain Stage 2 (residual) dissolution, leading to slower dissolution kinetics (Gin et al., 2013).

Ceramic hosts are typically very durable with respect to radiation tolerance (as are glasses (Radioactive Waste Management Limited, 2016)) and chemical durability (although there is some variation with ceramic type). The dissolution of ceramics is affected by the number of defect structures (e.g. oxygen vacancies) and grain boundaries, where higher occurrences can lead to enhanced dissolution (Corkhill et al., 2016), nevertheless much lower than glass dissolution. Glass-ceramics are heterogeneous wasteforms that can be advantageous for waste management: radionuclides typically partition in the more durable ceramic host, while the glass phase is chemically flexible and can easily accommodate variation in the waste composition. Glass-ceramics would be expected to undergo incongruent dissolution as a result of the different material properties associated with the glass and ceramic fractions, with the durability ultimately dependent on the least durable component.

Estimates for thermally treated wasteform dissolution rates in geological repository conditions vary dependent on specific wasteform chemistry, and groundwater conditions, however in average conditions they can be estimated to be between: 10^{-4} – $10^{-2} \text{ g m}^{-2} \text{ d}^{-1}$ for a borosilicate glass and 10^{-5} – $10^{-4} \text{ g m}^{-2} \text{ d}^{-1}$ for ceramics (Forschungszentrum Jülich and Brenk Systemplanung, 2011). For example, thermally treated ILW co-mixed wastes via in-can vitrification resulted in Si dissolution rates

(7–28 d) between 10^{-4} and 10^{-3} g m⁻² d⁻¹ (Walling et al., 2021a), while spent ion exchange materials converted into a glass-ceramic via hot isostatic pressing resulted in averaged dissolution rates (1–28 d) of 10^{-4} g m⁻² d⁻¹ (Si) and 10^{-5} g m⁻² d⁻¹ for Cs (simulant waste), where Cs was preferentially partitioned into the ceramic phase (Gardner et al., 2021), which broadly agree with the reported best estimate dissolution rates.

Overall, the performance of glass, ceramic and glass-ceramic wasteforms are deemed more durable with respect to aqueous dissolution than non-thermally treated wasteforms, however this enhanced durability should be assessed in conjunction with the higher facility costs of thermal treatment technologies, and the total risk associated with intermediate level wastes.

Summary

Overall, the majority of ILW treatment is currently undertaken by encapsulation using conventional Portland cement based blends, with the occasional exception for particularly challenging wastes. Cementation offers a durable, long-term solution with a high level of reliability, stability and understanding about long-term degradation mechanisms. Cemented products are generally radiation tolerant, have strong fire resistance and are ultimately very compatible with proposed construction methods for final geological repositories (especially with cement backfills). These reasons are likely to result in continued usage of cementation as an ILW treatment technology into the future.

Thermal treatment technologies provide advance processing for a wide variety of wastes, including those that may not be suitable for cementation in their raw format (e.g. organic materials, reactive metals). The variety of thermal treatment technologies vary in both scale and technological maturity, which may impact uptake within the nuclear industry. For example, induction heating and plasma heating are well-developed with existing industrial scale facilities, whereas the comparative maturity of hot isostatic pressing is currently much lower. The overall benefits for thermal treatment involve waste volume minimization to yield a stabilized monolith of either glass, glass-ceramic or ceramic that could be suitable for geological disposal, with very low dissolution rates under proposed repository conditions for both glasses and ceramics. There is an ongoing research and development drive to support the uptake of thermal treatment of ILWs via multi-partner consortiums in collaboration with end-users and the wider nuclear community. These projects are the 'Thermal treatment of radioactive waste minimization and hazard reduction' (THERAMIN; 2016–20) and the 'Pre-disposal management of radioactive waste' (PREDIS; 2020–24) with the overall aim to enhance strategic implementation of thermal treatment technologies for the management of intermediate level wastes.

Introduction

The operation of nuclear reactors, as well as their associated fuel cycles: uranium production, enrichment, fuel fabrication and reprocessing in some cases, generate radioactive waste. Radioactive waste also results from the use of radioactive materials in research, medicine, education and industry. In some countries, radioactive waste is also generated in support of defense activities. This means that practically all States have to consider the management of radioactive waste and to make sure it is managed in a safe manner with due regard to the level of radioactivity and in compliance with national regulations, often based on, or in harmony with, IAEA safety standards (AIEA, 2018).

High level waste (HLW) are waste with levels of activity concentration high enough to generate significant quantities of heat by the radioactive decay process and/or waste with large amounts of long lived radionuclides. Disposal in deep, stable geological formations usually several hundred meters or more below the surface is the generally recognized option for disposal of HLW.

Synthesis of the HLW typology and key characteristics

HLW typology

After use, Spent Nuclear Fuel becomes a highly radioactive material, due to the presence of minor actinides and fission products created by nuclear reactions. Spent Nuclear Fuel (SNF) is considered as a high level waste in some countries (United States, Sweden, Finland, Spain, Canada, etc.) or a potential future energy resource in others (France, Japan, United Kingdom, Belgium). In the first case, SNF will be disposed after some decades of interim storage ("once through fuel cycle"). In the second case, is planned to be reprocessed to recover fissile materials for future use ("closed fuel cycle"). The majority of States have adopted the policy of direct disposal of spent nuclear fuel, while several States with the largest nuclear programs (France, India, Japan, the Russian Federation, the United Kingdom and China) have adopted the policy of reprocessing nuclear fuel and recycling the separated material. Germany and the United States of America have changed their policy from reprocessing and recycling to direct disposal and are currently planning spent fuel repositories.

Basic characteristics of spent nuclear fuel (Poinssot and Gin, 2012)

A PWR spent fuel assembly is comprised of four 580-Lm thick Zircaloy fuel rods of 9.5 mm in diameter and 4-m long, inside which are stacked uranium oxide fuel pellets (Johnson et al., 1988). The free volumes of the fuel rods are initially filled with Heat 25 bar. After irradiation, the fuel pellets are fractured in roughly 15 fragments due to the presence of a steep thermal gradient and contain

minor actinides (produced by neutron capture) and fission products (produced by fission reactions), which are either trapped in the UO_2 lattice or remain present as metal or oxide solid phases within the UO_2 .

Part of the fission products are gases, which are for the larger part (95%) trapped within the UO_2 matrix, whereas the remaining gases are released in the free volumes of the rod and contribute to significantly increasing the internal rod pressure (up to 50–60 bar in room conditions). In addition, the distribution of fission reactions is not completely homogeneous within the rods and the zones with very high fission rates have a specific microstructure with smaller grains and a higher porosity. In the case of UOX rods, such zones occur as an external rim, and for MOX fuels, these zones occur in the Pu-rich agglomerates from the initial microstructure.

Furthermore, fuel cladding is also damaged during the in-reactor period due both (i) to the external corrosion by primary circuit water leading to hydrogen uptake, and (ii) to the irradiation-induced mechanical hardening. Finally, it is important to stress that nuclear fuel is not designed to be a durable waste form, but to host the fission reaction inside the reactor and to produce electricity. This means that it is severely damaged after irradiation and, furthermore, not in thermodynamic equilibrium due to the fast quenching upon reactor shutdown.

Therefore, its long-term durability and confinement properties are more difficult to demonstrate compared to a homogeneous and specifically-designed matrix such as nuclear glass.

Basic characteristics of high level liquid waste coming from SNF reprocessing

SNF contains about 2% fissile material (1% remaining ^{235}U , 1% plutonium and minor actinides) that can be isolated (reprocessed) and recycled as a new fuel. The HLW accounts for over 95% of the total radioactivity produced in electricity generation if a reprocessing policy is followed. It originates from a liquid residue from reprocessing spent nuclear fuel to extract the uranium and plutonium for reuse. The liquid contains most of the radioactivity from the original spent fuel.

In the reprocessing option, more waste streams need to be dealt with in addition to the HLW itself. These other waste streams include intermediate level structural waste such as hulls and nozzles from fuel assemblies, and intermediate level process waste, for example sludge from liquid effluent treatment. Typically, 1 t of reprocessed PWR fuel generates about 0.1 m^3 of HLW, 2.5 m^3 of ILW, $1.5\text{--}3 \text{ m}^3$ of LLW (all values are after conditioning, including the waste package/container) and 950 kg of uranium which can be reused for new fuel production (AIEA, 2018). The most important other waste streams produced in reprocessing spent fuel is the long lived ILW composed of the hulls and endcaps of the metal tubes that contained the fuel, and other parts of the fuel elements. These can be embedded in a matrix of cement inside a steel container or can be compacted into steel cylindrical containers similar to those containing the HLW.

Conventional aqueous (PUREX type—plutonium and uranium recovery by extraction) reprocessing generate a complex solution containing some 40 chemical elements which must be continuously stirred and cooled to dissipate its thermal power.

The fission product solution produced by the PUREX process is the initial highly radioactive liquid waste to be considered for conditioning. It is a nitric solution (typically 1–2 N) containing a complex mixture of species (about 100 g L^{-1}), partially precipitated, including mainly Cs, Sr, Mo, Zr, minor actinides (Np, Cm, Am), lanthanides, platinum group metals (Pd, Ru, Rh), plus alkaline and alkaline earth cations, and corrosion products from stainless steel, nearly the whole periodic classification.

Conserving this fission products solution in the liquid state is not a sustainable option considering security and safety concerns on the long-term, and this initial high level liquid waste (HLLW) have to be transformed to produce a chemically durable and heat- and radiation-resistant solid matrix tailored for final disposal nuclear glass wasteforms, as explained later on.

Rationale for selecting a relevant conditioning process

The conditioning of fission products solutions is aimed at (1) turning waste from the liquid to the solid state, (2) reducing the volume to be stored and, then, disposed of, and (3) getting a material which complies with the safety requirements peculiar to storage and long term disposal. More precisely, the conditioning material has to present satisfactory properties of resistance to self-irradiation (alpha, beta and gamma emitters), thermal stability (heat production associated with radioactivity), and chemical durability (taking into account environmental disposal conditions). The wasteform is meant to stabilize the waste during packaging, an interim storage period, transportation, disposal in a geological repository, and post closure disposal period. The deep geologic disposal is considered to be the most suitable option for disposing higher activity radioactive wastes worldwide because of the predicted effectiveness of many natural geological systems in reducing the transport of radionuclides that can be augmented by robust engineered barriers, thereby enhancing disposal facility performance.

Early research routes were first focused on mica- or feldspath-type crystalline materials prior to being re-oriented to vitreous materials in the late 1950s (Vernaz and Bruezière, 2014). During the 1960s, glass was selected by the world's community as the confinement material for fission products solutions, due to the structural flexibility of its disordered structure that enables glass to confine many chemical elements. The aim is not a mere embedding, but an atomic-scale confinement, since radionuclides are intimately incorporated in the glass structure.

Glasses were selected in the 1970s primarily for the following reasons (Jantzen and Ojovan, 2019):

- Vitrification technologies are known and reliable large scale non-nuclear commercial technologies.
- More cost-effective process than ceramics.

Fig. 1 Simulated non-radioactive nuclear glass.

- High solubility of waste components in the glass and tolerance to variation in waste composition.
- Low raw materials costs.
- Sufficiently high durability to ensure long-term performance.
- Continuous, high-throughput, operation of glass melters.
- High resistance to damage from radiation and radioactive decay.
- Reasonably well understood corrosion/release mechanisms for a homogeneous wasteform.
- Existence of natural analogues.

The use of the vitrification process (see [Fig. 1](#)) for conditioning of fission product has been chosen by many countries, such as France, Belgium, the United Kingdom, the United States of America, Japan, the Russian Federation, South Korea, India, China. Except for alkali-aluminophosphate glass used in Russia, alkali-borosilicate glass has been universally selected as the vitreous waste-form convenient for fission products solutions immobilization.

Determining a glass composition means making a compromise between the material properties and the technological feasibility of its industrial-scale fabrication ([Jantzen and Ojovan, 2019](#); [Vernaz, 2009](#); [Hyatt and Ojovan, 2019](#)).

The main following criteria are considered:

- Waste loading: the wasteform must be able to accommodate a significant amount of waste (typically 20 wt%) in order to minimize final volume of waste canisters to be disposed in deep geological;
- Industrial feasibility, considering that the processes need to be remote operated, in hot cells facilities.
- Durability: low rate of dissolution to minimize the release of radioactive and chemical constituents in the biosphere during very long period of time (typically 100,000 years), radiation stability.
- Compatibility with the intended disposal environment—compatible with the near-field environment of the disposal facility.

Description of the HLW conditioning processes, the sole industrially deployed conditioning process for HLW

Two kinds of industrial vitrification technologies are available: JHM, Joule Heated Melter and CCIM, Cold Crucible Induction Melters.

Fig. 2 Schematic drawing of joule Metallic Melter (left) and Liquid-Fed Ceramic Melter (right).

Two kinds of Joule Heated Melters are used in nuclear glass industry (Fig. 2):

- The ceramic melter, known as “LFCM” for liquid fed ceramic melter,
- Joule metallic melters.

The LFSM process consists in heating the glass by an electric current flowing between electrodes that are immersed in molten glass (approximately 1150 °C). The furnaces are big-sized ceramic furnaces, they show extended lifetime compared to metallic pots (several years). The melter is directly fed with the liquid waste, evaporation and calcination steps take place on the molten glass surface. This continuous process is implemented in Belgium (Pamela), United States (DWPF and WVDP), Japan (TVF), Russia (Mayak), India (Trombay) and Germany (CEK).

Joule Metallic Melter technologies for processing nuclear glass are implemented in France (Marcoule Vitrification facility, La Hague Facility), United Kingdom (WVP), India (Tarapur). The Joule heated melters are smaller than ceramic melters (containing typically 400 kg of glass), with a shorter lifetime, and metallic pot need to be changed after typically 1 year. They have a maximum operating temperature around 1150 °C. The vitrification process is a continuous two steps process, on line performed in two separate devices: evaporation-calcination of fission product solutions, and the vitrification of the calcinate previously produced. Heat is induced in the crucible walls, which heat the glass.

The CCIM is selected for processing glass or glass ceramic wasteform when higher melting temperatures (1200–1300 °C) are required. In this case, heat is directly induced in the molten glass and the crucible walls are cooled. There is a self-forming crucible, which is a thin cooled glass liner, a few centimeters thick, protecting the metallic walls of the furnace from molten glass corrosion. This technology is implemented industrially in France (La Hague facility), the induction melter being replaced by a CCIM on Fig. 2, and in Korean for low and intermediate level waste.

Typical nuclear glass compositions are given in Table 1 (Malkovsky et al., 2020) for countries that are industrially producing high level nuclear glass.

Vitrified waste interim storage

Background

The vitrified wastes are produced complying with product quality conditions (process conditions, glass chemical composition, thermal power, dose rate) which are the results of the optimization of production parameters, the interim storage conditions, the canister transportation and the final disposal facilities.

Table 1 Typical nuclear glass compositions.

NAP, Sodium Alumino Phosphate Glass; ABS, Alumino Boro Silicate Glass.

^aMiscellaneous includes waste oxides.

From Malkovsky VI, et al. (2020) The influence of radiation on confinement properties of nuclear waste glasses. Science and Technology of Nuclear Installations **2020**: 8875723, p. 14.

These high level waste canisters must be kept safe, whatever a decision concerning long-term disposal for HLW, interim storage is therefore worldwide necessary to manage glass canisters during several decades. In France for example, nuclear glass canisters (about 30,000 canisters) are safely placed in interim storage since the beginning of the industrial production (1978 for Marcoule Vitrification facility and 1989 for La Hague Vitrification facility).

The efficiency of the interim storage facility relies on the stability of the glass canisters and more especially of the glass itself, submitted specific thermal conditions (from 400 °C after production to less than 200 °C after 10 years) and submitted to a self-irradiation stress coming from the decays of fission products and minor actinides. Dose rate is around 1.4×10^4 Gy h⁻¹. Thermal heat is approximately 2.5 kW per canister at the production step, 1.6 kW after 10 years, and 0.6 kW after 50 years. After 100 years, ⁴³²Am (half-life period = 430 years) has a more and more important contribution to heat power in comparison to ¹³⁷Cs/^{137m}Ba and ⁹⁰Sr/⁹⁰Y radionuclides.

As an example, the French vitrified HLW canister is a steel canister 43 cm (17 in.) in diameter and 1.4 m (55 in.) in height (Fig. 3). The total volume is about 180 L (47.5 US gallons) and is filled with about 400 kg (882 pounds) of glass containing 65 kg (143 pounds) of HLW (about 15% to 18.5% in weight of FP and actinide oxides). US glass canisters produced at DWPF are larger, 10 ft tall and 2 ft in diameter.

After fabrication, glass canisters are cooled by a forced ventilation system. When thermal power is decreased (typically, < 2 kW for la Hague Facility), canisters are moved to an interim storage with natural air ventilation. The interim storage must guarantee that glass is kept at temperature lower than the glass crystallization temperature, which is depending on glass composition. In the case of borosilicate nuclear glasses, the minimum crystallization temperature is about 600 °C, and that is why the facility is designed to keep the canisters at temperatures lower than 500 °C.

Thermal stability

The nuclear glass are obtained by quenching of a glass melt prepared in the in the vitrification furnace. From a thermodynamic point of view, the glass at solid state is out of equilibrium conditions and could transform into a more stable form, a crystalline material. Crystallization phenomena in glassy materials obey to nucleation and growth laws that are limited by kinetic reasons. As an example, some studies performed on natural basaltic glasses have shown the preservation of the glassy state with no devitrification during the 1 million years of natural ageing after their fabrication (Crovisier et al., 2003).

In the case of the nuclear glass, specific studies have been performed on simulated and industrial nuclear glass to evaluate the risk of devitrification during the interim storage conditions. Long term thermal treatments have been performed, at 550 °C and 450 °C for 1 year, and have shown no crystallization of the glass. Moreover, some scientific studies were also performed to evaluate the nucleation and growth laws of the main crystalline phases that can be induced by thermal treatments in a temperature range of 630–1170 °C, either from isothermal or thermal gradient heat treatments (Orlhac et al., 1999, 2001; Delattre et al., 2013).

Optical microscopy and SEM experimental studies were used to determine the nucleation and growth kinetics of these phases. A modeling approach was developed to evaluate the crystallization rate of the glass with time and then applied in this temperature range. Three main crystalline phases have been observed, i.e., zincochromite, cerianite and powellite phases (Fig. 4). Taking into account the glass chemical composition a maximum of around 4 wt% of crystalline phase could be formed and would require an optimized thermal treatment. From the modeling work, the time necessary to induce a full crystallization of these phases is estimated to be of around 50,000 years at a temperature of 690 °C. This crystallization time increases by a factor of 100 with a decrease of temperature of 100 °C, meaning that at 200 °C, crystallization phenomena are negligible.

Fig. 3 Vitrified HLW canisters produced by ORANO La Hague (France).

Radiation stability

Nuclear glass are submitted to beta and alpha decays coming respectively from the radioactive decays of fission products and minor actinides, and also to gamma transition emitted by of the excited nucleus (Malkovsky et al., 2020; Mir et al., 2016, 2017; Weber, 2014). The beta decays, gamma transition and the alpha particles emitted in alpha disintegrations loss most of their energy to the glass structure by electronic excitation and ionization of the atoms. The recoil nuclei of alpha disintegrations mainly loss its energy by nuclear collisions with the atoms of the glassy network, inducing displacement cascades.

During the first 100 years of interim storage, the level of absorbed dose form beta decays and gamma rays is of typically around 4–5 GGy, and is called electronic dose. In the same time, the level of absorbed dose from the recoil nuclei of alpha decays is of around 0.02 GGy and is termed nuclear dose (See Fig. 5).

It has been shown that (Mir et al., 2016, 2017), under beta irradiation, simplified borosilicate glasses can undergo significant structural transformations, mainly involving point defect generation, boron coordination changes, modification of the glass polymerization level, changes of the mean angle between silica tetrahedral, and molecular oxygen formation. Nevertheless it was reported that the level of the structural transformation is influenced by the glass chemical composition. For instance, a mixed alkali effect appeared to decrease the changes, and the addition of transition metals or lanthanide elements into the glass can decrease or completely suppress the glass structure modification. It was suggested that the various redox states of transition metals

Fig. 4 Example of crystallization observed in a borosilicate nuclear glass after thermal treatment: zincchromite, cerianite and powellite are the white crystals surrounded by the glass which is darker.

or lanthanides act as traps for the electrons and holes generated by the interaction between the electrons and the glassy network, and consequently reduce or prevent the generation of point defects and any subsequent structural transformation. Therefore the chemical complexity of the glass is a positive factor that reduces its sensitivity to ionizing radiation. This certainly explains why few structural changes, with no modification of the glassy state, were observed in the studies of complex nuclear glass irradiated by beta particles up to 4 GGy.

Alpha decay accumulation in nuclear glass induces slight changes of macroscopic properties (density and mechanical properties), no modification of the glassy state with a glass microstructure that remains homogeneous without any phase separation and crystallization, a slight modification of the glassy structure, with modifications of both short and medium range orders (Peuget et al., 2014). The main structural changes are a partial conversion of boron from a tetrahedral coordination number to a trigonal one, an increase of the non-bridging oxygen atoms concentration and a modification of the ring statistic and angles in between the glass polyhedra. The final structure is the result of the ballistic melting in recoil nuclei tracks and the subsequent alpha particles partial damage repair due to a thermal self-healing mechanism in the alpha particles tracks. It results in a new homogeneous glassy state, similar to that obtained by a very high quenching rate of a molten glass, with slightly modified macroscopic properties. Their variations with dose is controlled by the accumulation of recoil nuclei track overlapping, according to a direct impact model. The saturation of the structural changes is therefore observed at a nuclear dose of around 40 MGy (or 4×10^{18} alpha decay/g) (Fig. 6).

The glassy state is preserved all along the duration of the interim storage period. Few structural changes and modification of the macroscopic properties are induced by both beta and alpha decays that are limited in amplitude and for which a saturation of the variation with dose have been observed. These results show that the main function of the glass that is to contain the radioactive isotopes will be preserved during the interim storage period.

Long term performance of HLW in geological disposal

Background

There is presently a broad consensus among technical experts that the preferred method of ensuring long term management of HLW (Spent Nuclear Fuel and Glass) is isolation in a deep geological disposal facility, which provides passive, multi-barrier isolation of radioactive materials from biosphere (AIEA, 2018).

Fig. 5 Evolution of the absorbed dose of a nuclear glass with time. The gray rectangle highlights the interim storage period.

Emplacement in carefully engineered structures buried deep within suitable rock formations provides the long term stability typical of a stable geological environment. At depths of several hundred meters, in a tectonically stable region, processes that could disrupt the disposal facility are so slow that the deep rock and groundwater system remain practically unchanged over hundreds of thousands or even millions of years.

In the geological disposal, high level waste packages will be exposed to underground water after several thousands of years, with ongoing corrosion of over- and primary containers, and that is why long term behavior of glass under leaching is widely described since decades. A schematic representation of spent fuel assemblies and glass package is shown on [Fig. 7 \(Poinssot and Gin, 2012\)](#).

In order to describe the long-term performance of waste forms, it is necessary to consider the different steps of their lifetime, in relation with the environmental conditions of the waste packages (wasteform, metallic containers and surroundings materials such as concrete and host rock, clay or granite).

Two boundary conditions are considered, associated with two scenarios.

- First situation: the waste package remain intact, without any interaction with the surrounding environment. The package undergoes only an internal modification and is exposed to energy exchanges involving heat and radioactivity (residual alpha, beta and gamma radioactivity and neutrons in spent fuel). No mass transfer occurs between the system and the external environment. These conditions are close to interim storage conditions.
- Second situation: the evolution of waste forms in a water-saturated open system. Once the leaktight container is breached, the waste matrix is subjected to aqueous alteration and can exchange matter with nearfield materials, such as cementitious materials and host rock. Migration of the radioactive elements then becomes possible.

A transient state between both of the above-described scenarios corresponding to the evolution of waste forms in an open unsaturated medium must also be considered, when the nearfield environment is not entirely resaturated with groundwater when canister breaches.

As a general rule, a waste form will successively undergo these three different types of boundary conditions. The first period corresponds to the lifetimes of the container and overpack.

Fig. 6 Structural evolution of the laboratory ISG glass doped with ^{244}Cm . (A) Raman spectra at two alpha decay dose, (B) Evolution of structural parameters with increasing alpha decay dose.

The occurrence of the open system/unsaturated conditions scenario will depend on the water re-saturation rate of the nearfield. It is therefore strongly site-dependent. It may last longer if gas bubbles (i.e., hydrogen) are produced due to metal corrosion (due mainly to the waste containers) and avoid the complete resaturation. At long term, the waste form will be placed in open and saturated conditions.

A simplified representation of the influence of the main physical and chemical parameters on spent fuel and glass source terms is given on Fig. 8 (Poinssot and Gin, 2012).

The water transport and solution chemistry are key factors regarding the long-term durability of both matrices. However, the mechanisms through which spent fuel and glass may release their RN are quite different. First, spent fuel is very sensitive to radiolysis whereas glass is not, second and most important, part of the RN within spent fuel are instantaneously released in contact with water (instant release fraction or IRF) whereas the RN in the glass are only released when glass dissolves.

Keys elements of the evolution of SNF in a repository (ref to be completed)

The RN release from spent fuel in contact with water, such as in a geological disposal site, can conceptually be broken down into two main fractions (Johnson et al., 1988). The first fraction involves the rapid release of the labile activity corresponding to the radionuclide inventory on the free surfaces of the fuel, and the release of the grain boundary inventory, over a period of several months to several years. This fraction is often referred to as the Instant Release Fraction (IRF). Quite interestingly, part of the radionuclides

Fig. 7 (Top): Schematic representation of a spent fuel assembly comprised of numerous fuel rods (center), which are made of an external Zircaloy cladding filled with UO_2 sintered pellets. After irradiation, these pellets are strongly modified (right). Bottom: schematic representation of a glass package (left) showing the primary canister made of stainless steel filled with borosilicate glass. Glass is fractured due to rapid cooling after the elaboration and forms a gel and crystalline phases when leached by water (center). At atomic level (right), glass displays an amorphous structure with a short range order. (Down): Schematic representation of a glass package (left) showing the primary canister made of stainless steel filled with borosilicate glass. Glass is fractured due to rapid cooling after the elaboration and forms a gel and crystalline phases when leached by water (center). At atomic level (right), glass displays an amorphous structure with a short range order. Poinssot C and Gin S (2012) Long-term behavior science: The cornerstone approach for reliably assessing the long-term performance of nuclear waste. *Journal of Nuclear Materials* 420: 182–192.

associated to IRF are anions which can be highly mobile in natural environments; Therefore, IRF significantly dominated to overall impact of spent nuclear fuel in geological disposal. The second fraction corresponds to the slow release of activity as the UO_2 matrix dissolves, and may last several thousands of years. The release of most of the activity from the spent fuel rod, i.e., the activity contained in the grains, is thus controlled by the fuel dissolution kinetics (Ewing, 2015; Jegou et al., 2007; Ferry et al., 2006; Kerleguer, 2020).

Key elements of the long term behavior of glass in deep disposal

The vitrification process involves chemically bonding radionuclides to an aluminoborosilicate network, except for a very small amount of them, which are retained in the small undissolved noble metal particles. From a long-term behavior point of view, this means that radionuclides confined in such a material cannot be released in the environment if the glass remains undissolved. More precisely, no instant-release fraction occurs for HLW glass, which is a very significant different with spent nuclear fuels. The

Fig. 8 Synthesis of the direct effects of the main constraints applied to waste forms in geological disposal sites (table) and their relative significance regarding the source term. Schematic representation of the main kinetic regimes of the spent fuel (up) and glass (down). Poinssot C and Gin S (2012) Long-term behavior science: The cornerstone approach for reliably assessing the long-term performance of nuclear waste. *Journal of Nuclear Materials* 420: 182–192.

solid-state diffusion process, even if thermally assisted, remains negligible. Radioactive decay produces heat and radiation damage and its potential effect is another key issue regarding the long-term stability of this type of waste form.

No significant impact of alpha/beta/gamma activity is expected on stage I (initial dissolution rate). For stage II corresponding to the residual rate regime, explored irradiation conditions seem to have very low effect both on the alteration rates and on the morphology of the alteration layer but some secondary effects can be observed such as modifications in the production of radiolytic species (Tribet et al., 2020). During glass alteration, RN are more or less retained in alteration products formed at the glass surface (gel and crystalline phases). The retained fraction mainly depends on the predominant redox form of each RN, which needs to be related to the water composition, the redox potential and the pH. The mobile fraction is made of aqueous species (potentially

promoted by ligands) and colloids. Many data are available in the literature for actinides and fission products (Gin et al., 2017), including some from integrated mockups and in situ tests, showing that under anoxic and reducing conditions expected in most of geological repositories, the solubility of most of long lives RN is very low.

Explaining the Long-Term Behavior approach requires identifying the governing mechanisms and developing models to over-estimate their influence (Poinssot and Gin, 2012; Ribet et al., 2009).

Glass alteration is described, whatever the glass composition, by the different reactions involved that are: interdiffusion (proton—alkali ion exchange), hydrolysis (Si—O—Si bond rupture), dissolved species recondensation so as to form an amorphous alteration gel which constitutes a diffusive barrier between the glass and the solution, and the precipitation of secondary crystalline phases.

These reactions are structured as four simultaneous processes which are likely to be described in terms of kinetics:

- the oxide glass is turned into a porous, hydrated, hydroxide-type phase (the gel);
- this glass hydration reaction is limited by the water diffusion transport into the pristine glass, through the gel layer already formed: in other words; the gel has a passivating effect;
- the gel is dissolved on its external surface at a rate which is a function of the solution composition and renewal conditions;
- secondary phases precipitate, thereby consuming passivating-zone formers.

At laboratory scale, the residual rate can be measured either thanks to static experiments at a high surface-to-volume ratio (S/V), or using a single-path-flow-through test at a low flow rate and a silica doped solution. When these protocols are applied to a large range of glasses, in most cases, a constant or a near-constant rate is observed, which is three to four orders of magnitude lower than the initial rate (the maximum dissolution rate corresponds to pristine glass in contact with pure water) and leads to rates of a few nm per year for UOX-type borosilicate glasses.

Modeling the long term behavior of nuclear glasses is needed to describe the glass alteration kinetics over a very large period of time, including the final residual rate regime, thanks to a mechanistic model such as the French GRAAL model (GRAAL meaning Glass Reactivity with Allowance for the Alteration layer) (Frugier et al., 2018; Poinssot and Gin, 2012; Frugier et al., 2008).

GRAAL is modeling the alteration of the glass, taking into account the evolution with time of the equilibria between the passivating layer, the secondary phases that may precipitate, and the composition of the liquid phase in interaction with the solid phases. Graal is correlated with a reactive transport model (such as HYTEC), and connected with a thermodynamical data base.

The long-term glass dissolution rate also depends on chemical and hydraulic factors that influence the fate of silicon. Silicon is the main glass former and this element is therefore involved in most of the chemical processes governing the glass dissolution process (Grambow and Müller, 2001; Gin, 2018). As the host rock is chosen for its low permeability and diffusivity, it can be expected that if the barriers placed in between the glass and the host rock do not prevent the saturation conditions with respect to the silica-rich passivating layer, the dissolution rate will be low. The low rate achieved when saturation conditions prevail is called the “residual rate” or “final rate.” These terms refer to the fact that no thermodynamic equilibrium between the glass and solution can ever be achieved and that no surface layer can completely protect the glass.

Performance assessment of geological nuclear waste repositories requires also modeling of the long-term evolution of the aqueous alterations of the fractured nuclear glass block, because the time scales under consideration are of several thousands of years and hence beyond the range of any direct experimental perspectives (Repina et al., 2020).

Furthermore, in situ glass corrosion experimentations on radioactive glasses have been carried out, giving some indications of the performances which are obtained for nuclear glass in representative repository conditions (see a review in (Gin et al., 2017)). Tests related to the geological disposal of intermediate and high level glasses have been carried out on three types of glasses with different compositions (borosilicates or aluminosilicates) in different natural environments, over several years. The results show very thin altered glass thicknesses, with the same orders of magnitude (a few microns) for the different glasses and environments, and typical of a process controlled by diffusion and point to the formation of a passivating alteration layer was observed, as observed for non-radioactive simulated glasses. Finally, accurate studies of archaeological or natural analogues demonstrates that the current nuclear glass alteration models are well predicting the order of magnitude of the overall alteration rates.

Development of alternative conditioning processes for HLW

A titanate-based fully crystallized wasteform, SYNROC, was invented by Australian scientists from ANSTO in the late 1970s (Ringwood et al., 1988; Gregg et al., 2020; Lutze and Ewing, 1988). The original form of Synroc, a multiphase ceramic wasteform based on stable and leach resistant titanate minerals was directed toward the immobilization of PUREX wastes from the reprocessing of nuclear fuels. Geologically stable titanate minerals—perovskite, hollandite, zirconolite and rutile are the main phases of Synroc.

The Synroc wasteforms are obtained thanks to HIPing processes. However, a current limitation is the lack of demonstration of this type of process at an industrially relevant scale within a nuclear facility.

Conclusion

The management of high level waste, spent nuclear fuel (SNF) and nuclear glass, is a key point in the nuclear industry, all around the world, since many decades, and for the future also. Two kinds of HLW need to be taken into account: SNF is considered as a high

level waste in some countries (United States, Sweden, Finland, Spain, Canada, etc.) or a potential future energy resource in others (France, Japan, United Kingdom, Belgium). In the last case, vitrification of the fission products coming from fuel reprocessing is the industrial process implemented in these countries, resulting in an industrial maturity which is now clearly demonstrated. Disposal in deep, stable geological formations usually several hundred meters or more below the surface is the generally recognized option for disposal of HLW. The description of the long term behavior of nuclear glass benefits from many international studies, showing that such glassy wasteform is quite relevant for HLW conditioning.

Glossary

AUC Ammonium Uranyl Carbonate (AUC) Conversion process of powders used for nuclear fuel pellet production.

Burnup Measure, how much energy is extracted from a nuclear fuel. It is a measure of the fraction of fuel atoms that underwent fission in megawatt-days/kg of heavy metal (MWd/kgHM), or similar units. Heavy metals are Uranium or Plutonium.

Dishing volume Dish like void space at the top and bottom of a nuclear fuel pellet to accommodate fission product swelling and axial thermal expansion of hot pellet centers.

Drip shield Massive shield made of corrosion-resistant titanium alloy, planned to be used in the Yucca Mountain nuclear waste repository project in the United States to protect spent fuel containing waste containers from seepage water dripping onto its outer surface.

Fluorite structure This structure refers to crystalline solids of the formula MX_2 like UO_2 , where the X ions occupy the eight tetrahedral interstitial sites and the M ions occupy the regular sites of a face-centered cubic (FCC) structure.

Half life The time it takes for the radioactivity of a specified radioactive isotope to fall (decay) to half its original value.

Ingestion toxicity The toxic effect of radioactive isotopes taken up into the human body for example by food.

IRF Instant release fraction: the fraction of inventory of radioactive isotopes released rapidly (days to month) from the used nuclear fuel upon contact with water.

Linear power rating The heat generation rate per unit length of fuel rod, commonly expressed in watts per m (w/m) of fuel rod.

LWR Light water reactor (nuclear reactor moderated by H_2O of normal isotopic composition).

MOX Mixed oxide fuel: Nuclear reactor fuel composed of UO_2 and PuO_2 , the latter obtained from reprocessing of spent nuclear fuels.

Radiolysis/radiolytic processes The splitting of water molecules by action of ionizing radiation, forming highly reactive radical and molecular radiolysis products such as $OH^\bullet$ or H_2O_2 . The radiolytic yields are different for alpha and gamma radiolysis. In the short time (up to hundreds of years) gamma radiolysis is dominant, in the long term, alpha radiolysis. Principal source for alpha radiation is the decay of actinides.

Source term Term describing the radionuclide release from spent nuclear fuel in case of groundwater access in a repository for nuclear waste.

UOX Nuclear reactor fuel composed of low ^{235}U enriched UO_2 .

Uraninite Uranium(IV) oxide (ideal formula: UO_2).

Vickers hardness The Vickers hardness gives the hardness of materials measured using a diamond indenter and a light load to produce an indentation on the material. The depth of indentation is converted into the hardness value of the object. The smaller the indentation, the harder the object.

Yucca Mountain Site for geological disposal of high-level nuclear waste in Nevada, United States. It is one of the few repository projects worldwide where geochemical conditions of natural waters are expected to be oxidizing. In most other repository concepts, reducing conditions are expected.

ε particle An agglomerate of metal alloy particles from the nanometer scale to the micrometer scale, containing mainly the fission products Mo, Ru, Tc, Rh, Pd and Te.

Introduction

The inventory of non-reprocessed spent fuel worldwide fuel has grown to some 250,000 metric tons corresponding to a total ingestion toxicity $>10^{13}$ Sv from its large contents of highly radiotoxic long-lived fission products such as for example ^{99}Tc

(half-life = 210,000 years), ^{129}I (16 million years) or ^{239}Pu (24,110 years). This stock is awaiting geological disposal to protect thousands of generations to come. Almost 50 years of research and repository planning have allowed characterizing the properties of spent fuel relevant for disposal safety, considering the factors of influence both in the fuel irradiation history as well as in the repository near field.

After reactor operation and 10 years of cooling typically about 4.4% of the initial Uranium content of typical light water reactor (LWR) fuel has been transformed to 0.9% Plutonium, 0.1% minor actinides (Am, Np, Cm), 0.3% radioactive Cs and Sr, and 0.2% long lived fission products like I, Tc and others and 2.9% stable fission products (Blue Ribbon Commission, 2012 for an average burnup of about 36 MWd/kgU for the a mix of PWR and BWR reactors). The decay of short-lived fission products will lead to a change over thousands of years in composition, radioactivity and heat production (Bruno and Ewing, 2006). Heat generation increases with fuel burnup and decreases over time. Evolution of heat generation and radionuclide inventories are typically calculated using nuclear modelling and simulation code packages like SCALE (Bearden and Jesse, 2018), using as input the initial fuel composition, the initial enrichment, considering the trace element contents of used materials, nuclear data libraries, the burnup and the irradiation history and the linear power ratings. Uncertainties can be about 2% for U and Pu contents, 7% for fission products and 11% for minor actinides (SKB, 2010a). Uncertainties in activation product (^{14}C , ^{36}Cl , ...) contents can be much higher as often no measurements are available and upper bounding values are obtained from maximal materials specification values for inactive trace impurities. Detailed burn-up and fuel charge history data are acquired from reactor operators before reliable calculations can be made to correctly dimension the heat load and emplacement distances to optimize space requirement in a nuclear waste disposal site. For equal burnup, heat generation is higher for MOX fuel than for UOX fuel. Cooling remains necessary even after 200 years of decay.

Radionuclide distribution in spent nuclear fuel

The radionuclides and non-radioactive fission isotopes are heterogeneously distributed in the irradiated nuclear fuel, as seen in Fig. 1.

The major amount of radionuclides are bound to the nuclear fuel matrix (UO_2), others accumulate at grain-boundaries, fracture surfaces, fuel plenum, dishing volumes or the gap between cladding and fuel (Ferry et al., 2005):

Fuel matrix: both in solid solution and at inter-lattice positions are located more than 99% of the actinides (Pu, U, Np, Am, Cm), rare earth elements, Ce, Nd, La, Pm, Pr, Sr, and some 80% to 90% of Xe, Kr (Ferry et al., 2005) and as well for He, Cs and I. These latter elements are rather volatile under reactor operation.

Grain boundaries: Many radionuclides accumulate in grain boundaries separating the typically about 10 μm large fuel grains. This includes fission gases and radionuclides of lower solubility in the fuel matrix such as $^{135,137}\text{Cs}$, ^{129}I , ^{90}Sr , ^{99}Tc .

Fig. 1 Schematic representation of the structure of spent fuel. Elements in red are released rapidly on first contact with water, while elements in blue are released more slowly as the UO_2 matrix corrodes (An = actinides and Ln = lanthanides in solid solution in the UO_2 structure). From Bruno J and Ewing RC (2006) Spent nuclear fuel. *Elements* 2 : 343–349. <https://doi.org/10.2113/gselements.2.6.343>, with permission from Mineralogical Society of America.

High burnup structure: this porous structure is formed due to high local burnup of ^{239}Pu , which is formed by resonance capture of epithermal neutrons on ^{238}U and beta decay at the fuel rim at an average burnup of about 60 GWd/tU following recrystallization of UO_2 grains. In case of MOX fuel, the high burn-up structure does not correspond to the rim but to the Pu rich islands within the U rich matrix.

Metallic inclusions like the ϵ particles are composed of the metallic fission products ^{107}Pd , Rh, Ru, Mo, ^{99}Tc alloy or (^{107}Pd , Te, ^{126}Sn) alloy or *oxide inclusions* of BaZrO_3 , formed from the fission products Ba and Zr. These particles have a size of few nm to hundreds of nm depending on the linear power and burnup under reactor operations.

Gap, void and fracture inventories: These include $^{135,137}\text{Cs}$, ^{90}Sr , ^{99}Tc , and ^{129}I . Fission gases in these volumes are released upon cladding failure during handling or disposal. Upon groundwater contact and cladding failure, these nuclides are first released, forming an instant release fraction IRF.

Cladding: These zirconium alloys with a zirconia (ZrO_2) surface and a crud deposit outside of the cladding include neutron activation products like ^{14}C or ^{36}Cl , alpha recoil nuclides, fission fragments as well as radioactive deposits (^{59}Ni , ^{63}Ni) from the primary coolant circuit.

Structural fuel parts: This includes both steel and Inconel, contaminated typically by ^{59}Ni , ^{63}Ni and ^{36}Cl .

Due to the absence of operational repositories for spent nuclear fuel today, an extended interim storage is necessary. Even though spent fuel is able to withstand long-term interim storage without major modification of its disposal relevant properties, some potential effects are of concern. Highest priority items are the stress corrosion cracking (SCC) of welded stainless steel (SS) canisters and the hydride effects (reorientation and embrittlement) of high burnup fuel cladding. Research items include the heat transfer (effects in SCC and temperature peak at drying) and the reorientation of hydrides of the cladding during the initial drying process and its relation with the Ductile Brittle Transition Temperature (DBTT) which is a key parameter regarding the transport after dry storage. Some of the processes might continue during disposal before contact of spent fuel with groundwater.

Alpha-decay damage is the dominating effect modifying the structure of spent nuclear fuel during long term storage prior to water access. The fluorite structure of UO_2 is preserved with an increase in lattice parameter (up to 0.6%), the formation of dislocation loops, the formation of helium bubbles and an increase of the Vickers Hardness. Bubbles are not expected to start forming in conventional spent fuel for several thousand years; however, in MOX fuels, they could begin forming within 1000 years (Wiss et al., 2014). High mobility of He bubbles is confirmed by natural analog uraninite samples of age of many 100 millions of years (Roudil et al., 2008).

In case of cladding failure and wet storage, many of the processes discussed further below for fuel water interaction under repository conditions apply. However, oxidizing conditions are generally expected in this case.

Long term interaction of spent fuel with water: Distinction between the instant release fraction IRF and release from fuel matrix

Most repository concepts for spent fuel worldwide foresee geological disposal in containers beneath the water table, resulting in container corrosion over periods of typically ten to hundred thousands of years (earlier for repositories in salt formations) producing by slow corrosion $\text{H}_2(\text{g})$ and $\text{Fe}(\text{II})$. After container breach, the initially very hot used fuel has cooled down and fuel immersion in water will occur at close to ambient temperature. The cladding is very stable in water and protect the fuel from groundwater contact probably for some additional tens of thousands of years. However, since no statistically relevant study of long term cladding stability has been conducted, current safety assessments do not take credit from cladding tightness and assume cladding breach with container breach exposing the spent nuclear fuel to water. An exception is Yucca Mountain/Nevada, where the protection by the cladding is taken into account (Ahn and Mohanty, 2008). Corrosion by groundwater of cladding and structural materials will lead to leaching of activation products like ^{14}C (partially organic), $^{59,63}\text{Ni}$ or ^{36}Cl . The corrosion of Zircaloy under repository conditions and the associated radionuclide release were discussed in Johnson and McGinnes (2002). After removal from reactor, the cladding (thickness of about 600 μm) contains a thin oxide film of tens of μm of ZrO_2 . Suggested maximal corrosion rates are about 10 nm/year.

The interaction between spent fuel (without or with defect cladding) and groundwater ("leaching") is being studied since more than 45 years. Early results show (1) that the leach rate decreases from $\text{Cs} > \text{Sb} > \text{Sr} + \text{Y} > \text{Pu} > \text{Cm}$ with about 1% of the inventory of Cs^{137} being released (Katayama, 1976), (2) that the fractional release rate of Pu decreases over many orders of magnitude in few days and (3) that release rates are relatively insensitive to temperature (Johnson, 1982). The concentrations of both U and Pu attain saturation rapidly in aqueous solutions contacting spent fuel and the leaching rate for Sr^{90} decreased from about $10^{-5}/\text{day}$ to $10^{-7}/\text{day}$ but remained higher than for U, Pu, Cm, Ce, Eu and Ru. In reducing geochemical conditions, expected in European repository concepts, significantly lower release rates are attained (Forsyth et al., 1986) due to low solubility of many radionuclides including uranium.

Other, more water-soluble radionuclides do not attain solubility. Release kinetics vary over time, from the first groundwater contact after container breach to over hundreds of thousands of years of water contact, distinguishing between radionuclide specific release from the fuel matrix, from gaps, from accessible grain boundaries, from cladding and structural metals. A major conceptual choice traditionally made lies in codifying this heterogeneity by only two sources of release: the fuel matrix and an instant (or fast) release fraction, IRF, representing everything being released faster than the matrix. Schematically the temporal evolution of these sources of release are given in Fig. 2. A fraction of a given radionuclide content of the fuel may be attributed to the matrix, the other

Fig. 2 Typical model for long term radionuclide release with instant release (IRF) and fuel matrix contributions. IRF values are considered independent on environmental conditions but depend on spent fuel irradiation history, matrix contributions depend principally on the oxidation state of the environment.

is conceptualized in the IRF. Two type of IRF constituents are distinguished: those, which under reactor operation have similar volatility as fission gases and, hence, their mobility is linked to fission gas release, FGR, others are independent of FGR. Accessible fractions of grain boundary inventories may count as IRF, inaccessible ones count in the matrix. In some rare cases (Ferry et al., 2005), IRF(t) values for different time scales are given, accounting for diffusion toward low-performance microstructure before water ingresses the canister.

The release from the fuel matrix is controlled by the dissolution rate of the UO_2 (or UO_2/PuO_2 in case of MOX) matrix of the fuel. Release rate control by matrix dissolution is relevant for all radionuclides dispersed in the fuel matrix: those being in solid solution but also those in metallic or oxide precipitates dispersed in the fuel matrix and even those being incompatible with the fuel matrix like gases, trapped after fission or alpha decay (He) in the fuel grains.

Assessment of the IRF inventory as a function of spent nuclear fuel characteristics and irradiation history

The IRF inventory varies significantly with spent fuel characteristics. After Helium as alpha decay product and the fission gases, the most mobile elements in the fuel both under reactor conditions and after cool-down are iodine, tellurium and bromine, the rare gases and cesium. IRF inventories for $^{135,137}\text{Cs}$, ^{36}Cl and ^{129}I are strongly linked to FGR due to diffusion coefficients in the fuel (Walker and Lassmann, 1986). Indeed, transport from grain center to grain-boundaries is governed by thermal diffusion at the hot fuel centerline and by slower radiation assisted athermal diffusion beyond about mid-radius. Grain-boundaries provide further pathways across the fuel. This leads to much higher FGR, $^{135,137}\text{Cs}$, ^{129}I and probably ^{36}Cl release from the hot fuel center and since thermal diffusion in the fuel rod central region is strongly depending on temperature gradients under reaction operation conditions, IRF and FGR are strongly linked to linear power as already observed for ^{137}Cs very early (Eklund and Forsyth, 1978). With increasing burnup and formation of the high burn-up rim structure (Fig. 2) an acceleration of FGR is observed (Mogensen et al., 1999; Brémier et al., 2000). The ratio of IRF to FGR has been observed to be about 1:3 ratio for $^{135,137}\text{Cs}$ and 1:1 for ^{129}I (Johnson et al., 2004, 2012). These ratios are linked to ratios of diffusion coefficients of the fission products in the UO_2 matrix. However, in contrast to fission gases, no accelerated release of IRF nuclides was observed from the high burnup region (Fors et al., 2009; Serrano-Purroy et al., 2012; Johnson et al., 2012). The same absence of accelerated diffusion from the HBR zone (the Pu islands, Fig. 3) is observed for MOX fuel (Carbol et al., 2009b).

The European project “FIRST-Nuclides” (Lemmens et al., 2017; Kienzler et al., 2015) has studied the fast release of fission gases, $^{135,137}\text{Cs}$, ^{129}I , ^{14}C , ^{79}Se , ^{99}Tc , ^{126}Sn , etc. from gap and UO_2 grain boundaries, identifying a clear link to reactor operation conditions such as burn-up, power rating and calculated fission gas releases. Abnormally high fission gas release and IRF values were observed for abnormally low density fuels like ATM-106 as well as for fuels with high linear power ratings.

A mechanism contributing to the IRF is grain-boundary release. The IRF was anticipated to grow in the early 2000s due to diffusion mechanisms, which was finally not supposed to be significant enough. Diffusion coefficients in grain-boundaries are orders of magnitude higher than in the matrix. Distinction of gap and grain-boundary contributions to the IRF values were attempted by Serrano-Purroy et al. (2012).

After about 0.5–1 year the release rates of Cs and I are in the same order of magnitude as observed for matrix dissolution. Due to the operational definition of the IRF value, a clear relation between the observed IRF of redox sensitive elements and elements incorporated in the UO_2 matrix has been observed, demonstrating the effect of the leaching conditions, allowing a better definition of the transition between both release mechanism: Fast release can also be due to fast dissolution of the fuel matrix. Moreover, matrix

Fig. 3 SEM examination of the periphery ("rim") of a UOX pellet (left) and aggregates in AUC MOX fuel after three cycles (burnup ≈ 30 GWd/t) 1200 μm from the edge of the fuel (right) (Ferry et al., 2005).

^{135,137} Cs	1	1	2.5	6.1	7.8

^aAfter the publication of Johnson et al. (2005) it became evident by new data that in contrast to gases, other fission products are effectively retained in the high burnup rim zone and no preferential release is observed. The values of Johnson et al. (2005) were initially kept forward in Grambow et al. (2008) as pessimistic values, but in the present table, the pessimistic values for Sn, Tc, Pd, Se are omitted as evidence is clear (see references in this paper) that there is no preferential release from the HB rim zone. As in Johnson (2014), only fission gas released to gap was used as reference for Cl, Cs and I release data, using average fission gas data from figure 3.2 in Johnson et al. (2004). To account for model uncertainties in representing release from grain-boundaries, an additive factor IRF contribution of 4% was added by Johnson (2014) to the IRF values of Cs and I, corresponding to the fission gas inventory in the rim zone at a burnup of 60 GWd/tU. As the grain boundary inventory is much lower at lower burnup, the values in SKB (2010b) were used for lower burnup.

oxidation tends to open grain boundaries and thus causes the continuous exposure of fresh grain boundaries with high concentrations of soluble IRF nuclides (Kienzler et al., 2015).

Various models are described in literature to assess the contribution of IRF values to the source-term of spent nuclear fuel in the performance assessment of nuclear waste repositories. A model considering all known uncertainties at the time was developed (Poinssot et al., 2005a) attributing no confinement properties to grain-boundaries, high burnup structure and gap. Grain boundary inventories are in general lower than gap inventories (Johnson et al., 2004). Using the above-mentioned relations between FGR and Cs and I release, best estimate and pessimistic gap release values were suggested as a function of burnup, as well as grain boundary inventories including the high burnup rim porosity. However, it has been shown that actually release from the rim zone is lower from the rim than from the center of the fuel. The data were corrected with some more recent approaches and insights to calculate IRF values for various nuclides as a function of burnup (see Table 1). For example, recent literature indicates the absence of fast release of Se (Johnson et al., 2012) bounded by a maximal fast release of $<0.2\%$, explained by direct binding of Se to U in the fuel matrix (Curti et al., 2015). For MOX fuel best estimate IRF values are also obtained from fission gas release values (Johnson et al., 2004).

Assessment of the matrix dissolution behavior, role of radiolytic oxidants, hydrogen and near-field buffering

The dissolution of the UO_2 matrix is the condition for the release of matrix bound radionuclides into groundwater and it provides as well an upper limit for the dissolution of nano-crystalline phases like the ϵ phases, finely dispersed in this fuel matrix. In case of

Fig. 4 Evolution of alpha and beta radiations as a function of time for a 55 GWd/t UOX fuel. Data are calculated from the CESAR isotopic evolution code. Reprinted from Poinssot C, Ferry C, Lovera P, Jegou C, and Gras J-M (2005b). Spent fuel radionuclide source term model for assessing spent fuel performance in geological disposal. Part II: Matrix alteration model and global performance. *Journal of Nuclear Materials* 346 : 66–77. <https://doi.org/10.1016/j.jnucmat.2005.05.021>, with permission from Elsevier.

oxidizing conditions there is surface oxidation from U(IV) to U(VI), relatively fast dissolution as described by Schortmann and De Sesa (1958), Grandstaff (1976), and Leider et al. (1991), accelerated dissolution in presence of carbonate, formation secondary reaction products like schoepite $((\text{UO}_2)_8\text{O}_2(\text{OH})_{12} \cdot 12\text{H}_2\text{O})$, studtite $(\text{UO}_4(\text{H}_2\text{O})_4)$, Uranophane $(\text{Ca}[(\text{UO}_2)_2(\text{SiO}_3\text{OH})]_2 \cdot 5\text{H}_2\text{O})$ or becquerellite $(\text{CaU}_6\text{O}_{19} \cdot 11\text{H}_2\text{O})$. Reversely, under reducing conditions expected for European repository concepts, dissolution of the fuel matrix is extremely slow, the solubility being controlled by UO_2 (about 10^{-10} M) and a potential phase transformation to coffinite (USiO_4) (Ewing, 2015). As the solubility and water flow rates are very low the release rates of matrix bound radionuclides shall remain also very low.

However, it became evident (Forsyth et al., 1986; Christensen et al., 1994; Christensen and Sunder, 2000) that the radiation field can lead to oxidative spent fuel dissolution even in globally reducing environment. The interrelation between the electrochemistry of oxidative dissolution, of solution chemistry and radiation field is reviewed in detail by Eriksen et al. (2012). Radiation decomposes water molecules, forming very reactive radical $(\text{OH}^\bullet, \text{HO}_2^\bullet, \text{e}_{\text{aq}}^-, \text{H}^\bullet)$ or molecular radiolysis products $(\text{H}_3\text{O}^+, \text{H}_2, \text{H}_2\text{O}_2)$ depending on the nature of the radiation field (α , β or γ) and on the deposited dose. The radiation dose will decrease over time and α -radiolysis will become dominant in the long term (see Fig. 4).

The radiation field of actual spent fuel is very strong and not representative for the radiation field expected for 1000-year-old fuel. To simulate long-term spent fuel behavior in water, alpha doped UO_2 can be used. Radiolysis provides a strong source for oxidation of UO_2 to UO_{2+x} (Sunder et al., 1990) allowing for oxidative dissolution in presence of groundwater species like carbonate ions. There is a threshold dose, below which alpha radiation is unable to sustain oxidative dissolution (Poinssot et al., 2006), see Fig. 5.

The threshold depends on environmental conditions. A higher dose threshold is obtained in the presence of H_2 gas formed by container corrosion. Indeed, the dissolution rates even of fresh spent fuel dropped in presence of H_2 by four orders of magnitude, when compared with oxidizing conditions (Röllin et al., 2001), see Table 2.

With H_2 concentrations as low as 5.9×10^{-6} M, the oxidizing effect of radiolysis and in particular of formed H_2O_2 is completely blocked by galvanic coupling with the ϵ phases (Wu, 2014) and low dissolution rates are observed, as expected under reducing conditions. Reduction of radiolytic oxidants and of slightly oxidized UO_2 to $\text{UO}_{2.00}$ occurs as well by activation of H_2 on a UO_2 surface without ϵ -particles (Carbol et al., 2009a). Solution concentrations of uranium are controlled by the solubility of UO_2 . For the other radionuclides incorporated in the spent fuel matrix, the solubility of UO_2 is also a boundary limiting maximum solution concentration. Behavior in cementitious environment is similar to that in neutral groundwaters (Lemmens et al., 2019). The interlinked processes leading to spent fuel dissolution are illustrated in Fig. 6.

In the presence of failed cladding, the dissolution rate decreases significantly, probably due to mass transfer resistance (Wilson, 1990), studying the corrosion of cladged spent fuel with cladding defects in form of a slit (0.015 cm diameter/2.5 cm length) or a hole (0.2 mm diameter) in oxic Yucca Mountain water at 85 °C. This lead to a decrease of dissolution rates by up to 2 orders of magnitude for Tc99, Sr90 or I129. No such effect is expected under reducing conditions, as corrosion rates are much slower, implying a lower significance of rate controlling mass transfer.

Various models have been developed describing fuel matrix dissolution for the source term in the context of the performance assessment of nuclear waste repositories. The model uncertainties have been assessed in the MICADO project (Grambow et al., 2011). The models typically consider (1) the generation of oxidants by a radiolytical model considering radiation field and

Fig. 5 Threshold activity of the spent fuel for alpha radiolytic enhanced oxidative dissolution (Poinssot et al., 2005a).

Table 2 Typical spent fuel matrix dissolution rates for various environmental conditions, if necessary: fractional dissolution rates converted using a typical external specific fuel surface area of 2 ± 1 cm/g (Grambow et al., 2011).

type, (2) oxidation of the spent fuel surface, and (3) dissolution of the spent fuel matrix and radionuclide release according to the uranium speciation and groundwater composition with or without consideration of electrochemical processes and solution complexation. Conservatism was established by ignoring radiolytic reductants (Poinssot et al., 2005b) or only considering H₂O₂ as radiolytic reactant. A small list of typical models is given in Table 3.

Recent simulations (Liu et al., 2017) have demonstrated that H₂O₂ is the primary radiolytical oxidant driving spent fuel corrosion. The simultaneous radiolytical production of H₂ and its activation on ϵ -phases, rapidly lead to the suppression of this rapid corrosion reaction to insignificant radiolytical rate values (i.e. $< 10^{-20}$ mol/m²/s). Radiation dose rate, the H₂O₂ decomposition ratio, and the surface coverage of ϵ particles all influence the time necessary to achieve these very low corrosion rates. As for natural uraninite, one can conclude that non-oxidizing UO₂ dissolution rates become dominant in reducing repository conditions being controlled either by the very small solubility of UO₂ or a dissolution/precipitation or dissolution/sorption reaction involving dissolution of spent fuel and precipitation of a U(IV) solid phase like coffinite. Isotope dilution tests have been used to investigate the role of precipitation or sorption on the dissolution rate of UO₂ under expected reducing conditions (Fe). While ²³⁸U concentrations in static dissolution tests correspond to the theoretical solubility limit of UO₂ in granitic water (10^{-10} M), isotope dilution indicated continued dissolution with a very low rate 10^{-6} g/m²/year, see Table 2 (Ollila, 2008). These data suggest that a UO₂ solubility

Fig. 6 Schema describing the processes interlinked in the dissolution of the spent fuel matrix (IRF not taken into account).

controlled dissolution model is not conservative when describing the long-term release of matrix bound radionuclides from spent fuel under reducing conditions.

A best estimate of dissolution rate has been obtained (Werme et al., 2004) from the measured very low solution concentration (around 10^{-10} M) at the end of a long-term static tests in reducing waters, assuming that the release rate is linear. This method overestimates the long-term release rate since in all cases, where testing with expected H_2 concentrations has been conducted, the dissolution rate decreases with exposure time. This approach has shown that there is indeed no enhanced dissolution due to alpha radiolysis under the conditions that will pertain in a repository in granite formations. Matrix dissolution rates of relevance to soluble fission products and to actinides from spent UO_2 fuel are given as a triangular distribution with a range from 10^{-6} to 10^{-8} per year with a peak at 10^{-7} per year (Werme et al., 2004). While the dissolution rate of MOX fuel of moderate burnup is about 7 times higher than of UO_2 based fuel, the uranium oxide matrix of the spent MOX fuel appeared to be the main contributor to the measured dissolution in the presence of H_2 , while the corrosion of the high burnup Pu rich islands were negligible (Carbol et al., 2009b). Many radionuclides will have much lower release rates as expected from the fuel dissolution rate due to solution control by solubility or coprecipitation (Metz et al., 2012) in secondary alteration products. There was some discussion as to whether the release from spent fuel under reducing conditions is rate controlled or solubility controlled. However, recently (Grambow et al., 2017) it has been shown that both processes are linked and have the same physical-chemical origin: the kinetic interpretation of solubility equilibrium involves equal sorption/desorption rates, which in case of UO_2 involve much less than the dissolution of an atomic layer on the solid. With a maximum reaction rate of 10^{-6} – 10^{-8} /year for matrix bound radionuclides and a solubility of dissolved U of 10^{-10} M more than 99% of released Uranium will be immobilized again, hence one shall call this process spent fuel conversion and not fuel matrix dissolution as in SKB (2010b). The above mentioned continued isotopic exchange on UO_2 surfaces despite solubility equilibrium (Ollila, 2008) cannot be used as proof signifying that there is a significant solid state transformation despite UO_2 saturation as it may only involves restructuring of few surface sites on UO_2 . This does not rule out a dissolution/reprecipitation mechanism driving release of matrix bound radionuclides, for example by coffinite formation, but since less than a mono-layer is involved in this exchange (Grambow et al., 2017), the distinction between sorption and precipitation has only semantic character. And if the UO_2 or MOX surface is thermodynamically stable under reducing conditions, other elements like Tc, Mo, Np, Pu and Am initially released from the fuel actually are observed to decrease their concentration in solution to values $< 10^{-9}$ M and not to increase it (Fig. 3.29, Carbol et al., 2005).

Summary

Forty years of research have shown the very high kinetic and thermodynamic stability of the spent fuel under reducing geological disposal conditions. One can conclude that due to the high fuel matrix stability even in presence of radiation fields, overall release of radiotoxic elements from the spent fuel in a repository under reducing geochemical conditions is largely dominated by release of the IRF inventories. In repositories in clay-rock, it is in particular the release of ^{129}I which will be dose limiting to future generations living in the vicinity of the disposal location, yet largely inoffensive to any health impact. While reliable estimations of ^{129}I release can be made today as a function of burnup and linear power, it would be useful to have a larger data set for fuels of different irradiation histories to reduce the overall uncertainties when deriving maximal ^{129}I release data from available gas release data. In contrast, for oxidizing repository environments like those targeted for Yucca Mountain in Nevada, United States, while expecting similar release of ^{129}I , much higher release of matrix bound actinides and Tc is expected upon immersion as the dissolution rate of the fuel matrix is about 1000 times faster (see Table 2). In the absence of intrinsic fuel stability, other factors like a protective role of the cladding or a drip shield need to be taken into account to assure high spent fuel stability.

Table 3 Typical models used to describe spent fuel dissolution.

<i>Model description</i>	<i>References</i>
Model 1: The Matrix alteration model (MAM) was developed during the SFS and MICADO project by Amphos21, CIEMAT and ENRESA, considering water radiolysis, geochemical solution and surface complexation reaction (kinetics), calibrated with a large set of data on UO_2 dissolution as a function of pH, H_2O_2 and carbonates concentration, successfully applied α doped UO_2 and spent fuel. The effect of hydrogen on spent fuel dissolution rates is described as a homogeneous effect in bulk solution.	Martinez Esparza et al. (2005)
Model 2: The H_2O_2 model was developed by KTH. It considers water radiolysis and diffusion of species and heterogeneous kinetics at the SF surface, making the hypothesis that only H_2O_2 production leads to spent fuel oxidation, and all oxidized spent fuel was conservatively considered as being dissolved. Hydrogen effects are described by catalytic interaction with the epsilon phases.	Trummer and Jonsson (2010)
Model 3: of SUBATECH considers water radiolysis and diffusion of radiolytic species with the radiolytic transport code Tramo, considering dose gradients at the fuel surface. The water radiolysis model and electrochemical surface reactions are coupled. The effect of H_2 is described by an effect on the corrosion potential.	Grambow et al. (2011)
Model 4: of CEA is the French operational source term model. It considers primary radiolytic species. It assumes that 50% of the oxidizing species will be able to hit the fuel surface leading instantaneously to oxidation and dissolution of the fuel as U(VI) . It is a mass balance approach without fitting parameters.	Poinssot et al. (2005b)
Model 5: Describes the impact of H_2O_2 and of H_2 from container corrosion (activated on ϵ particles) on spent fuel dissolution, considering diffusion of O_2 , H_2 , H_2O_2 and UO_2^{+2}	Liu et al. (2017)

Introduction

Since the 1950s, there has been an international effort to develop deep-mined geological repositories for the disposal of highly radioactive nuclear waste. At least 10 countries (Canada, China, Finland, France, Germany, Japan, Sweden, Switzerland, United Kingdom and United States) have major efforts underway that have already lasted for decades. Significantly, as of 2020, no country has opened a geologic repository for the disposal of the spent fuel from nuclear power plants used to generate electricity. Among those making the greatest progress are Finland, Sweden and France. Other countries, such as Canada, Germany, United Kingdom and the United States, have had to delay or “reset” their programs, mainly to address political and public opposition (NWTRB, 2015; Metlay, 2016; Ewing et al., 2018).

The earliest recommendations for the disposal of nuclear waste date from the mid-1950s, when a U.S. National Academy of Sciences (NAS) Committee first presented a report (NAS, 1957), *Disposal of Radioactive Waste on Land*. Prior to this, many fanciful solutions, such as deep space disposal or technological solutions, such as accelerator-drive transmutation, were considered. The basic principles from the NAS (1957) report were affirmed again 20 years later (NAS, 1978). Among many ingenious alternative strategies proposed for disposing of some or all of the nuclear waste inventory, geological disposal remains the only one that appears to offer safe, long-term disposal of highly radioactive waste types: spent nuclear fuel and solidified high-level waste from reprocessing. The first thoughtful scientific analysis of requirements for developing a deep-mined geologic repository was by earth scientists (Bredehoeft et al., 1978). Their prescient paper recognized the importance of different waste types, the challenges of site characterization, the perturbations that the emplaced waste would impose on geologic formations, and the time frames over which geologic isolation would be required.

Nuclear nations in western Europe and elsewhere also began to plan for geological disposal in the late 1970s and 1980s. Most countries have interacted through the International Atomic Energy Agency (IAEA), which has established safety requirements for the disposal of radioactive waste (IAEA, 2011a) and developed guidance on how geological disposal facilities should be built (IAEA, 2011b).

The United States was the first country to embark on this journey, and thus, is illustrative of the challenges all countries have faced in implementing programs of nuclear waste disposal. The earliest concern in the U.S., in the late 1940s, was for the fate of the high-level waste from reprocessing fuel from plutonium production reactors. The wastes were part of the Manhattan Project at the Hanford and Savannah River sites in the states of Washington and South Carolina, respectively. A committee of the U.S. NAS recommended disposal in a deep mined geological repository, specifically in salt formations (NAS, 1957). From 1963 to 1972, the Atomic Energy Commission (AEC) conducted studies of a salt dome near Lyons, Kansas, but finally, had to abandon the effort for both technical reasons and political opposition. A three-year effort by an interagency review group culminated in the Nuclear Waste Policy Act (NWPA) of 1982 (Carter, 1987). The NWPA was a comprehensive covenant that outlined the role of three U.S. agencies: Department of Energy (DoE) as the implementer; Environmental Protection Agency (EPA) to set the standard; and Nuclear Regulatory Commission (NRC) to implement the standard and regulations in order to review the application for construction and disposal submitted by the DoE. States were given a lesser role of “consultation and concurrence.” The NWPA 1982 required the characterization of multiple sites and the development of two repositories, east and west of the Mississippi river, and a method of funding derived from a fee levied on electricity generated by nuclear power plants that went into a Nuclear Waste Fund (NWF). The federal government was to have taken ownership of commercial spent fuel in 1998 for transport to and final disposal in a geological repository.

In 1987, the NWPA was amended such that only Yucca Mountain in Nevada would be carried forward for characterization. Despite strenuous objections by the state of Nevada, the Yucca Mountain project went forward, and a license application was submitted in 2008, a decade after the federal government was to have taken ownership of the commercial spent fuel. In 2009, the Obama Administration attempted to withdraw the license application, describing the Yucca Mountain site as “unworkable.” During the past decade the fate of the Yucca Mountain project has been mainly in the hands of Congress and Federal courts, and work has not continued. A more detailed description of these recent events can be found in Ewing et al. (2018).

Other countries have had their own unique histories, mainly starting in the 1970s. A history of 10 national programs was published by the Nuclear Waste Technical Review Board (NWTRB, 2015). In nearly all cases, however, the development of a geologic repository has been very difficult.

For all nuclear waste programs, there have been four fundamental challenges:

- **Models:** The development and application of credible physical and chemical models of the projected behavior of a repository is challenging. Natural systems are notoriously difficult to model. In evaluating a geologic repository, models necessarily include spatial scales that begin at the atomic-level with the corrosion of spent fuel to scales of tens of kilometers in order to consider the effects of hydrologic and tectonic events, such as earthquakes, volcanism and climate change (Nordstrom, 2012; Konikow and Bredehoeft, 1992).
- **Time:** Typically, the projected behavior of a repository extends to hundreds of thousands of years in order to assure safety to the environment and humans. However, these time scales are on an evolutionary time scale, comparable to the time over which the human species has evolved. Additionally, boundary conditions, such as climate, hydrology and human geographic distribution patterns and habits, which change over time, can have a huge effect on the outcome of model simulations.
- **Exposure:** The evaluation of the impact of a geologic repository on the human population out to hundreds of thousands of years is a major technical challenge. The calculation of dose to a population far into the future requires many assumptions, such as the

health effects of low doses of ionizing radiation, as well as the determination of exposure pathways to populations into the distant future.

- *Public acceptance:* Finally, public acceptance of the results of the technical analysis, already difficult enough, depends on the development of a strategy for public engagement and power-sharing that is not accounted for in most national programs or, indeed, the governance structure of most countries.

Despite these challenges, a number of useful approaches have been developed for the evaluation of the long-term performance of a geologic repository over the past decades. In terms of the models, one may use a range of parameter values that are conservative. Regarding future boundary conditions, a variety of scenarios should be investigated. The long periods of the analysis and the complexity of natural systems also imply that studies of natural systems, so called “natural analogue” studies, and experiments in underground research laboratories are useful in providing confirmatory guides of projected performance. The use of exposure as a metric of compliance can be supplemented by using multiple measures of performance as embodied in the safety case approach. Finally, some countries have developed successful strategies of public engagement that involve joint planning and power-sharing.

Types of radioactive waste

The types of waste intended for geological disposal depend on the type of nuclear fuel cycle adopted in each country, whether the country has a nuclear weapons program, and the way different radioactive materials are classified. Waste types are of three broad categories (Ewing et al., 2016): (i) highly radioactive, heat-producing waste, which mainly includes spent nuclear fuel and high-level waste from reprocessing of spent nuclear fuel; (ii) less radioactive waste materials contaminated by long-lived nuclides, such as plutonium. This is generally termed long-lived intermediate level waste in Europe or transuranic waste in the U.S.; (iii) low-level waste, mainly contaminated by short-lived radionuclides, generated by medical procedures and reactor operations. The first two categories are generally destined for deep, mined geological disposal, whereas the third category is suitable for disposal in shallow, landfills.

For geologic disposal, the important issues for developing a repository are: (i) the radionuclide inventory; (ii) the evolution of this inventory over time; (iii) the geochemical mobility and radiotoxicity of the radionuclides in specific disposal environments; and (iv) the thermal output of the waste. The challenge for geoscientists is to understand how the evolving conditions (e.g., thermal and radiation fields, as well as hydrologic conditions) of a repository affect the geochemistry and mobility of the radionuclide inventory, which is also changing over time. The decay of one radionuclide often becomes the source of another (e.g., ^{239}Pu with a half-life of 24,100 years decays to ^{235}U with a half-life of 700 million years).

Most deep-mined geological repositories are for the disposal of heat-producing spent fuel or high-level waste from reprocessing, but there are important variations within each of these waste types. For spent nuclear fuel, the type of fuel, burn-up and age since removal from the reactor all have an impact on the radionuclide inventory and the thermal output (Hedin, 1997; Ewing, 2015). For high-level radioactive waste, the type of chemical processing and the age of the waste are important. Reprocessing generally lowers the content of long-lived actinides, but it leaves high concentrations of shorter-lived fission products, such as ^{137}Cs and ^{90}Sr . Although these shorter-lived fission products have half-lives of approximately 30 years, they are responsible for the large thermal output, which determines how long the waste must be stored at the surface prior to disposal. There are also very long-lived, problematic radionuclides, such as ^{129}I , ^{99}Tc and ^{79}Se . These complexities mean that countries with a long history of nuclear power plants and nuclear weapons programs have a wider variety of wastes that require different treatments and handling; countries with waste from only commercial nuclear power plants have much less complicated waste streams.

The basic tenets of geological disposal

Multiple barriers

A major tenet of radioactive waste disposal is the concept of multiple barriers (Ewing et al., 2016; Yardley et al., 2016). This “belt and suspenders” approach envisions a series of barriers, each with a capacity to prevent or slow the release of radionuclides. The objective is not to fully contain the waste forever, but rather to delay radionuclides reaching the biosphere so that most will have decayed away, or so that dilution and sorption onto the geologic media during transport have lowered concentrations in groundwater, thus lowering subsequent human exposure to well below regulatory limits. The multi-barrier concept is a precautionary approach in the face of the huge uncertainties that result from projections of physical and chemical processes over large spatial (tens of kilometers) and temporal (hundreds of thousands of years) scales. If one barrier fails to perform as expected, other barriers should provide for a margin of safety. Barriers are of two types: engineered and geologic (Ewing et al., 2016).

Engineered barriers

Engineered barriers include the waste form, the waste package, and surrounding backfill. Most of the engineered barriers are physical in that they delay the access of water to the waste package (e.g., the drip shields proposed at Yucca Mountain) or the release of

radionuclides from a breached canister (e.g., the bentonite buffer in the KBS-3 concept for granite repositories (see [Hedin and Olsson, 2016](#))). In some cases, the engineered barrier has a chemical function, affecting the geochemical environment around the waste. For example, MgO is emplaced with the transuranic waste in the bedded salt repository at the Waste Isolation Pilot Plant (WIPP) in New Mexico, and a high pH cement was developed in the United Kingdom to encapsulate intermediate level waste. In both cases, the intention is to remove CO₂ and provide an environment in which the solubility of actinides remains low.

Waste Form: Although the most common waste forms for highly radioactive materials are spent nuclear fuel and vitrified high level waste, there are many other types of waste forms ([Lutze and Ewing, 1988](#); [Weber and Ewing, 2013](#)). A summary of the characteristics and recent developments in waste form research can be found in [Ewing \(2006\)](#). The properties of the waste form can be of critical importance, as the waste form initially contains *all of the radioactivity*. To the extent that the waste form is durable, and the release of radionuclides is low, the remainder of the safety analysis is less challenging. One approach is to tailor waste form properties to match either the composition of the waste stream or the geologic conditions of the waste form in the repository. As an example, the UO₂ in spent nuclear fuel is unstable under oxidizing conditions, but much more stable under reducing conditions. Also, the corrosion rate of the borosilicate glass is slower when the silica concentration in the groundwater is higher, although other chemical components can lead to accelerated corrosion. The properties of the waste form also change as the temperature and radiation field evolve with time ([Ewing, 2015](#)). Radiation damage mainly from the alpha-decay of actinides can lead to radiation-induced phase transformation from the crystalline to amorphous state ([Ewing and Weber, 2010](#)).

Waste Package: The waste form is typically placed in a metal canister, which may consist of steel, copper or more advanced corrosion resistant alloys. In many countries, the waste producers (i.e., utilities) are required to package waste in standard packages that the repository is designed to accommodate. Some countries intend to follow the Swedish KBS-3 concept, in which spent fuel is placed in iron insets that are then placed in copper containers. These are then inserted into holes drilled into crystalline rock and overpacked with bentonite clay. Intermediate level wastes are commonly encapsulated in cement in stainless steel or iron canisters, and a diverse range of cements have been proposed.

Back-fill or overpack: In order to reduce water movement through a repository after closure, the remaining void space must be filled with a material compatible with the engineered and geological barriers. Bentonite backfill for heat-producing waste canisters has been investigated extensively, but for larger waste volumes, host rock materials and cement are likely to be important. Repositories in salt will employ crushed salt, which will gradually be compacted as the excavated rooms close. Uniquely, the proposed repository at Yucca Mountain does not utilize a backfill ([Swift and Bonano, 2016](#)).

Geologic barriers

Geologic barriers rely on the properties of the rock and hydrologic system around the repository and are intended to extend the travel time required for radionuclides to reach the biosphere. The movement of fluid through the rock is controlled by its hydraulic conductivity, which depends on its matrix permeability and the presence or absence of fracture systems. Irrespective of the movement of groundwater, the mobility of the radionuclides in solution may be further retarded by precipitation of radionuclide-bearing phases, sorption onto mineral surfaces, and matrix diffusion (a process by which radionuclides are “trapped” in the micro-sized void spaces in the rock). In other cases, the movement of radionuclides can be accelerated by sorption onto colloids and advective transport or due to the formation of negatively charged chemical species: such is the case for ¹²⁹I, that are repelled, rather than sorbed, from mineral surfaces. Mineral surfaces have a negative charge; hence there is no sorption of negatively charged species in solution.

All proposed repository sites to date are located below the water table, with the exception of the Yucca Mountain site in Nevada, where the proposed repository is in the unsaturated zone ([Swift and Bonano, 2016](#)). The apparent “dryness” of the unsaturated zone is complicated by a high infiltration rate, large volumes of water held in the porosity, and rapid flow along fractures. For disposal below the water table, the host rock must have a low permeability to ensure that radionuclides released from containers over time do not reach the biosphere. Three types of host rock are widely recognized as having the potential to provide a sufficiently low permeability to meet this safety requirement: strong rocks with very low porosity and very few fractures (including igneous, metamorphic and even some sedimentary rocks, see for example, [Hedin and Olsson \(2016\)](#)); relatively weak mudrocks or clays, which will not sustain open fractures for extended periods of time ([Grambow, 2016](#)); and rock salt, which is also self-sealing ([von Berlepsch and Haverkamp, 2016](#)). The rock must also have the necessary physical properties for the construction of the repository. In some cases, as in granite, high mechanical strength favors construction, but the presence of fracture systems may increase the hydraulic conductivity. In other cases, such as salt, a medium level of mechanical strength may be advantageous as plastic deformation and flow of the salt seal the rock that surrounds the waste packages.

Thus, the petrophysical, geochemical and hydrologic properties of the geologic formation have an important impact on the strategy that is adopted for the complementary engineered barriers. Also, there are important interactions among the engineered and geologic barriers. As an example, the geochemistry of the groundwater at the repository horizon may buffer its geochemical properties, which in turn, affect the rates of canister and waste form corrosion.

The physics and chemistry of the safety assessment is essentially an evaluation of the effectiveness of the barrier systems over time, complicated by the coupled and evolving thermal, radiation, hydrologic and geochemical conditions of the repository. The strategy for handling the heat of the spent nuclear fuel and high-level waste will also dictate the disposal strategy and the choice of barriers. Aged-waste in smaller packages can reduce the thermal pulse in the repository, which is important if a clay backfill is used. On the other hand, larger packages and a larger thermal pulse might be used to drive water away from the surface of the waste package. Very high heat, however, can affect the condition of fuel cladding, a thin metal alloy wrapped around the fuel pins, which

in some concepts is considered as a barrier. Additionally, the safety assessment must consider regional aspects of the geology, such as seismicity and volcanism and even climate change and glaciation. The presence of natural resources in a region must also be considered, as the exploration for and extraction of resources can compromise a geologic repository.

Geological repositories

From the scientific perspective, considerable amount of basic research and site characterization have been completed in a variety of rock types—clay, salt, crystalline rock, and volcanic tuff. For each rock type, the scientific and engineering strategy is different—driven by the properties of the different geological formations, the types of waste to be disposed of, and the regulatory requirements of each country. Indeed, there is now a huge literature on all aspects of nuclear waste management and disposal ([Ahn and Apted, 2010](#); [Lee et al., 2013](#)).

Salt

The concept of disposal in bedded salt or salt domes dates back to the 1957 study and recommendations of the U.S. NAS. The earliest effort was at a salt dome near Lyons, Kansas, but this failed due to technical issues (e.g., an incomplete understanding of the previous drilling and mining activity) and political opposition.

Disposal of low and intermediate nuclear waste in Germany has favored salt domes ([von Berlepsch and Haverkamp, 2016](#)). Nuclear waste has been disposed of at the Endlager für radioactive Abfälle Morsleben (ERAM) site, a previous salt mine, in the former East Germany, but disposal of waste was discontinued in 1998. In addition, some 125,000 drums of low and intermediate level waste were disposed of in 13 chambers at depths of approximately 750 m in what had previously been an operating salt mine at Asse II in lower Saxony in the former West Germany. Disposal and research ended in 1995, due to the ingress of water into the mined cavities. Whether to retrieve the radioactive waste or leave it in place remains a major political and difficult technical issue. Another site in lower Saxony, Gorleben, has been the subject of research and development from 1979 to 2000. A moratorium on work at Gorleben was declared in 2000.

The U.S. has successfully developed a deep-mined geologic repository for transuranic defense waste at the Waste Isolation Pilot Plant (WIPP) in southeastern New Mexico. The mine was licensed for the disposal of nuclear waste for a compliance period of 10,000 years and began receiving transuranic waste on March 26, 2019. To date, some 12,700 shipments of waste have been received at WIPP from 22 transuranic sites in the U.S. The repository is in a 910 m thick layer of bedded salt, and the disposal horizon is at 660 m below the surface. In February of 2014, there was a minor release of radioactivity from a breached waste package due to an exothermic reaction of waste package contents. The repository was closed for 3 years. Operations at WIPP resumed on January 9, 2017. In 2020, WIPP is the only operating deep-mined geologic repository in the world.

The advantages of disposal in salt are three-fold: (i) Salt is self-healing via a process of creep, which closes open fractures and porosity, leading to extremely low permeabilities. Waste packages become sealed in the salt, although due to lithostatic pressure, such as at WIPP, the drums of waste will be crushed and breached. (ii) Salt domes and bedded salt deposits have low concentrations of water. The age of many salt deposits, that is hundreds of millions of years, speaks to their stability and the absence of freshwater. (iii) Salt has a high thermal conductivity as compared to typical silicate-based rock formations. For HLW with heat-producing radionuclides, the heat is more quickly dissipated away from the waste package.

The disadvantages of salt include: (i) Salt is soluble in fresh groundwater. (ii) Thermal pulses induce fluid inclusions to move toward and concentrate around the waste package. (iii) Brines are exceptionally corrosive of metal waste packages. (iv) Hydrogen gas evolves from the corrosion of metal waste packages, leading to a buildup of gas pressure. (v) Bedded salt formations are not entirely homogeneous and often contain thin layers of clay or other mineral salts that can open and provide access to water or release of radionuclides. (vi) Salt deposits are often in areas of important mineral resources, such as potash, oil and natural gas. Inadvertent intrusion by drilling programs for resources may penetrate the repository horizon. Thus, the main barrier to release of radionuclides depends on estimates of the drilling rates in the area at distant times and an understanding of the chemistry of brine solutions, particularly the solubility of radionuclides in brines.

The chief barriers to radionuclide release in salt formations are the absence of water, although brines are commonly present in bedded salt deposits, and the physical sealing of the waste by the salt that surrounds the waste. Waste packages and waste forms are not considered barriers to release. The chemistry of the salt plays only a limited role in radionuclide retention. At the WIPP site in New Mexico, thousands of pounds of MgO have been added to the disposal galleries in order to moderate the chemistry of the brine and prevent the formation of CO₂ created by microbial activity in order to reduce the solubility of plutonium in the brine ([Tracy et al., 2016](#)).

Clay

A number of countries pursue disposal in clay, claystone or shale. Clays are very fine-grained, silicate minerals with a sheet structure that has the ability to expand and absorb water or radionuclides. The expansion of a clay leads to a substantial reduction in porosity and permeability. At the present, three countries, Belgium, France and Switzerland, have active site investigations in clay formations ([NWTRB, 2016](#)).

The main advantages of clay include ([Grambow, 2008, 2016](#); [NWTRB, 2016](#)): (i) Expanding clays, such as bentonite, are effective seals to the ingress of water. (ii) The very small grain size (millimeters to micrometers) provides substantial surface area onto which radionuclides may be sorbed. (iii) The corrosion of canister materials, such as iron, will produce a hydrogen gas that slows down the movement

of water toward the canister. (iv) Ground water in clay formations is saturated in silica, which reduces the corrosion rate and radionuclide release from vitrified waste. (v) In case radionuclides are released, some actinides and ^{99}Tc will be sorbed onto the iron corrosion products of the canister or the clay surfaces of the surrounding backfill and rock. Additionally, the presence of organic carbon in shales will maintain reducing conditions that curtail the mobility of actinides and other redox sensitive radionuclides. The release of more soluble radionuclides, such as ^{139}I will depend on the rate of corrosion of the waste form, although the complete dissolution of vitrified “logs” in breached canisters is expected to take many hundreds of thousands of years (Grambow, 2016). Even for radionuclides that do not readily sorb onto clay mineral surfaces, the mobility of radionuclides in a clay formation is diffusion-controlled, a much slower process than transport by moving ground waters, i.e., advection. (vi) Although clay formations can be faulted or experience fracturing, clay formations typically deform plastically, filling open spaces; thus, clay formations generally retain their low permeabilities.

Potential disadvantages of clay include: (i) Clay formations are heterogeneous with a variety of types of clay minerals whose physical and chemical properties vary. (ii) Non-sorbing radionuclides, such as ^{129}I , ^{36}Cl and ^{79}Se can diffuse through the clay formation until reaching other formations with faster groundwater transport. (iii) As with salt, shale formations, particularly organics shales, are often related to the formation of hydrocarbon deposits; hence, there is the possibility of inadvertent human intrusion due to the search for natural resources.

The chief barriers to radionuclide release in clay formation are both physical and chemical. The physical barriers are related to the low porosity and permeability that reduce the mobility of radionuclides. The chemical barriers involve the reduced corrosion rate of glass in silica-saturated groundwater, redox conditions that reduce the solubility of key radionuclides, and chemisorption of radionuclides onto mineral surfaces.

Crystalline rock

Crystalline rock refers to both igneous and metamorphic formations that consist of tightly interlocked grains of minerals that have formed by crystallization from a melt or solid-state reactions at elevated pressures and temperatures. For the purpose of the disposal of nuclear waste, granites, gneisses and basalt formations have been considered in Canada, China, Japan, United Kingdom, Russia and the United States—but the concept has been developed in its most advanced form in Sweden and Finland. The basic KBS-3 concept in Sweden consists of a series of barriers around the spent fuel: metal, zircaloy cladding that surrounds the UO_2 fuel pellets, a copper canister with a ductile iron insert that holds individual fuel assemblies, a bentonite clay backfill around the copper canister, and emplacement in crystalline rock (Fig. 1). The concept has been modified in other countries, such as in Russia, where an iron alloy is envisioned for the waste package (Laverov et al., 2016).

Fig. 1 The Swedish KBS-3 concept for the disposal of spent nuclear fuel (SKB, 2006). The spent fuel assembly is placed in iron inserts that are then placed into copper canisters and the whole package is then surrounded by bentonite clay and deposited at approximately 500 m depth in groundwater-saturated granitic rock. The system of multiple barriers include: (i) low corrosion rate of spent fuel under reducing conditions; (ii) low corrosion rate of the copper canister under anoxic conditions; (iii) the swelling bentonite clay slows the ingress of water to the copper canister and reduces the mobility of any released radionuclides due to the very low permeability of compressed bentonite; (iv) the slow flow of groundwater and sorption of radionuclides onto mineral surfaces delays entry to the biosphere. SKB (2006) *Long-Term Safety for KBS-3 Repositories at Forsmark and Laxemar—A First Evaluation*, Report No. TR-06-09, Swedish Nuclear Fuel and Waste Management Company: Stockholm, Sweden, pp. 27, 613 pages.

The advantages of the KBS-3 strategy in crystalline rock include (Hedin and Olsson, 2016): (i) Because of the high strength and rigidity of crystalline rock, tunnels and rooms remain open, resisting deformation due to glacial epochs or earthquakes. (ii) The disposal level is below the water table, which helps mitigate the effects of climate change on geohydrological conditions. (iii) The redox conditions are generally reducing due to the presence of sulfides in the crystalline rock, hence lowering the solubility and mobility of some key radionuclides, such as the actinides. (iv) Sites can be located where the chance of exploration for economic mineral or energy deposits is low. (v) The waste packages are emplaced at relatively low temperatures, no higher than 100 °C, which maintains the stability of other barriers, such as the bentonite. (vi) The use of a backfill, such as a 35 cm thick mixture of mainly bentonite, can delay the ingress of water to the canister and reduce the mobility of radionuclides that might at some distant time be released from a breached canister. (vii) The engineered barriers are made of natural materials, such as copper, thus providing evidence of their stability over geologic periods.

The principal challenges of the KBS-3 concept include: (i) The need to characterize the flow of groundwater through fractures in the crystalline rock. (ii) The possibility that the bentonite backfill or buffer might be “washed-out” due to flowing groundwater. (iii) The potential for copper canister corrosion, a subject of some recent controversy (King et al., 2010; Taxén and Bergqvist, 2019).

The safety strategy of the KBS-3 concept relies on an evaluation of the compatibility of all of the materials in the various barriers systems and their passive performance in the absence of human intervention. The primary barrier to release of radionuclides is the copper canister, which is expected to have a lifetime of many hundreds of thousands of years. Great care has been taken to preserve the integrity of the copper canisters, such as by using two techniques, electron beam welding and friction stir welding of the lids to the canister body in order to mitigate the possibility of strain-induced corrosion that results from normal welding techniques. The addition of backfill is meant to slow the ingress of water to the canister surface, and the low temperature at the surface of the canister reduces the rates of chemical reaction. The secondary barrier, in the event the first barrier is breached, is the crystalline rock itself and its interaction with any exposed fuel elements. This is not expected to occur until far into the future when the fuel is much cooler and most of the radioactivity has decreased substantially (Hedin, 1997). That said, the challenge of understanding the chemical interactions between the UO₂ in the fuel, the corroded canister, and the surrounding rock is substantial. A number of the relevant processes for the release of uranium are illustrated in Fig. 2.

Volcanic tuff

Volcanic tuff consists of fragments of material and ash ejected during a volcanic eruption. During compaction and cooling from a high temperature, a harder “welded” tuff can form. Tuff typically has a high porosity created by escaping gases during volcanic eruptions. Tuff can be fractured due to cooling and contraction and has a medium structural strength, but still is able to support the construction of tunnels.

The U.S. is unique in its effort to construct a repository in the volcanic tuff at Yucca Mountain, some 145 km northwest of Las Vegas, Nevada. There are a number of unique aspects to the U.S. approach: (i) The repository is “hot”, that is the surface of the waste packages is above the boiling point of water as part of a strategy for delaying the contact of water with the surface of the waste package. (ii) The geochemical conditions are oxidizing. (iii) The disposal horizon is some 200 m above the water table. (iv) There is no backfill, but rather the tunnel space is left open for ventilation and the dissipation of decay heat from the relatively large waste packages; waste packages will be protected from water by a titanium drip-shield.

The advantages of volcanic tuff at Yucca Mountain (Swift and Bonano, 2016) include: (i) Yucca Mountain is located in an arid region and approximately 200 m above the water table in the unsaturated zone. The dry climate and closed hydrologic basins are believed to limit transport of radionuclides. (ii) There are two very important engineered barriers: a corrosion resistant nickel-based alloy, Alloy-22, that is highly resistant to general and localized corrosion in an oxidizing environment; a 1.5 cm thick titanium drip-shield that will be placed over the metal waste packages in order to divert and delay any intermittent seepage from percolating groundwater. (iv) The very limited and distant population reduces the possibility of radiation exposure.

The disadvantages of this strategy (Ewing and Macfarlane, 2002; Macfarlane and Ewing, 2006) include: (i) Yucca Mountain tuff is not dry. The very high porosity, 10–40 vol%, retains water, much as a sponge does. Additionally, rapid water movement along fast paths of transport, fractures, has been identified by the detection of “bomb pulse” ³⁶Cl at the repository horizon. The rapid transport of ³⁶Cl occurred over less than a half-century. (ii) Oxidizing conditions lead to the relatively rapid breakdown and alteration of UO₂ to uranium oxyhydroxides, some of which have low solubility constants or lead to the formation of colloids that can transport radionuclides (Novikov et al., 2006). (iv) A hot repository causes the movement of water around the disposal tunnels and can accelerate the corrosion of the waste packages due to the presence of deliquescence-induced corrosion of the waste package. (v) Yucca Mountain region is located in the Basin and Range province of the western U.S., typified by volcanic and seismic activity.

Conceptually, at Yucca Mountain, the main barrier to the release of radionuclides is the absence of water in this arid region. The secondary barrier consists of the engineered barriers, waste package and the drip shield. Finally, the very long distance, 20 km, of transport slows the time and amount of radioactivity that can reach the nearest inhabited area, Amargosa Valley, a small farming community of less than 2000 people. This strategy means that the entire transport distance is part of the geology barrier, and the principal means of reducing the total radioactivity are radioactive decay, sorption onto mineral surfaces and dilution.

Fig. 2 Chemical processes that may affect the alteration of spent fuel in contact with groundwater. Schematic representation of spent fuel alteration mechanisms and mechanisms controlling radionuclide concentration in solution in the near-field environment of the fuel, including groundwater, corroded waste package and backfill (if present), as well as the surrounding rock (Ewing, 2015). This schematic deals mainly with the fate of uranium from the SNF, but a similar understanding has to be developed for the release of each radionuclide that is released due to the bulk dissolution of the SNF. Each radionuclide will have its unique chemistry and fate over the long-term corrosion process. Ewing RC (2015) Long-term storage of spent nuclear fuel. *Nature Materials* 14: 252–257.

Deep borehole

The concept of deep borehole disposal involves, as the name indicates, the emplacement of waste down a borehole, usually < 50 cm in diameter, to depths as great as 3–5 km. The fundamental strategy is based on the concept that “deeper is better” in that there is geologic evidence for the long-term isolation of very deep groundwater, usually brines, from the surface. The concept requires remote emplacement and the absence of backfill or thick-walled waste packages, due to the need for the waste package to fit into the small diameter hole. There are a number of variations on this strategy, in some cases the emplaced waste packages are stacked in a vertical hole or emplaced horizontally by directional drilling. The temperature of the waste package may be low or high, depending on the age of the fuel and the geologic formations used for emplacement. Critical to the success of the approach is the need to guarantee that the borehole can be sealed over the course of hundreds of thousands of years. One very novel approach to sealing the hole has been the proposal to use the decay-heat of the spent fuel to melt the surrounding silicate rock, such that, once cooled, the waste would be entirely encapsulated in solid rock (Gibb and Travis, 2015).

The earliest discussions for the use of deep boreholes for the disposal of radioactive waste date from the 1950s (NAS, 1957) as a possible solution for the disposal of the HLW created by fuel reprocessing for the production of plutonium at the Hanford site in Washington. Studies in Sweden (SKB, 1992, 2010) and the United Kingdom (NIREX, 2004) reviewed borehole disposal in detail as part of a consideration of alternatives to the disposal of spent fuel in a deep-mined geological repository. The concept has been periodically revived in various forms (Gibb et al., 2012; Brady et al., 2012; Bates et al., 2014; Bracke et al., 2016; Cornwall, 2015; Krall et al., 2020). Two companies, Deep Isolation (<https://www.deepisolation.com>) and NuclearSAFE (<https://nstusa.net>) have been the most recent proponents of deep borehole disposal, both proposing the use of horizontal emplacement of canisters containing spent fuel.

In addition to the great depth of the disposal horizon and depending on the strategy adopted, there are other barriers to limit the ability of the radionuclides to reach the surface from a deep borehole. These include: (i) the density stratification of deep fluids, usually brines, should prevent advective, upward flow; (ii) at depth, permeability of the rock decreases due to the lithostatic pressure; and (iii) geochemical conditions are reducing.

The challenges to deep borehole disposal include: (i) Remote emplacement and retrievability in the event of an accident, such as the breach of a canister; (ii) Even very deeply seated rock units can display considerable heterogeneity in physical, chemical and petrologic properties. The required level of characterization for a safety assessment may not be possible at such great depths; (iii) The approach emphasizes the geologic barriers at the expense of the use of engineered barriers. A truly multi-barrier system may require chemical processing to incorporate the waste into a durable waste form or the use of waste packages that can withstand the pressure, temperature and corrosive effects of brine at depth; (iv) The plug in the borehole must not fail, as it is the main pathway for fluids, which are under pressure, to move upward. There are also important operational concerns with handling, emplacement, inspection and retrieval during the emplacement operation. A detailed discussion of these issues can be found in Krall et al. (2020).

In the final analysis, deep borehole disposal may require the same level of scientific site characterization, engineering innovation and performance analysis as a deep-mined repository. That said, deep borehole disposal may be useful for disposal of unique waste streams, such as radioactive sources or fissile material from dismantled nuclear weapons.

Multi-barrier disposal systems

Based on the brief summaries of the different disposal strategies in different geologic regimes associated with different rock types, one can recognize that there are very different approaches to the barrier systems for different types of geologic repositories. In some cases, the geologic barrier is preeminent, and in others, the waste package is the primary barrier to release. All of these systems have multiple barriers, but the evaluation of safety will depend on the robustness and redundancy of the barriers over appropriate time scales.

Retrievability and reversibility

In response to public concern and skepticism about the strategy of permanent geologic disposal, two new concepts emerged in France in 1991 as part of the French Radioactive Waste Act and were analyzed as part of the Andra report, *Dossier 2005: reversibility and retrievability* (Andra, 2005). The NEA (2001, 2010) has reviewed the factors involved in the application of these concepts.

Reversibility refers to the ability to reverse any one of a series of steps in the development of a geologic repository. This requires an iterative, stepwise review during the process of characterization and construction of a geologic repository. At any specific step, new knowledge, such as that developed during characterization of the disposal horizon, may require changes in the strategy envisioned for the role of the engineered barriers or require more detailed investigation of the geologic barriers. An example of the latter is in the early history of WIPP project in the U.S., for which the site location was shifted in order to avoid disturbed rock units that were revealed by the early drilling program.

Retrievability is a special case of reversibility as it requires the removal of already emplaced nuclear waste. This may be the result of new knowledge or the discovery that waste packages do not meet regulatory requirements. Over the longer term, new policies and standards may justify the need to retrieve the waste: (i) the waste may become a valued resource; (ii) standards of safety may change

and become stricter; (iii) better technical options may be developed; (iv) some waste may be reclaimed to confirm behavior during disposal in order to confirm the models used in the safety assessment.

There is a tension between the concept of permanent geological disposal in which the passive operation of the engineered and geological barriers contains the waste and delays the release and the time of arrival of radionuclides to the biosphere. In contrast, reversibility and retrievability require active engineering interventions at the disposal site. These interventions may disrupt the efficacy of certain barriers and must be considered in the design of the barrier systems (e.g., ensuring that barrier systems and, if necessary, the waste packages can be removed as needed). This judgement will be challenging, as one must weigh the exposure and environmental effects of retrieving waste in the near term against exposure and environmental effects in the long term. Generally, it is understood that with the passage of time, the role of the passive barriers increases, while the possibility of reversibility or retrievability decrease.

Site selection

As illustrated in the description of different strategies in different rock types, the multi-barrier approach is adopted in different ways. In some instances, the primary barrier is the geology, such as in a clay repository, and in others, the primary barriers are the engineered barriers, such as highly corrosion-resistant waste packages that utilize copper or the nickel-based Alloy-22. In all cases, the strategies involve multiple barriers, but the role of engineered versus natural barriers has an impact on the approach to site selection.

Since site selection is one of the most controversial steps in developing a geologic repository, it is important to understand how criteria are developed and applied in this process. From the technical perspective, there are three types of criteria (NWTRB, 2015):

Exclusion Criteria: These criteria can be used to eliminate areas based on broadly applicable concepts (NAS, 1957). Resource-rich areas might be excluded due to the possibility of future exploration for and extraction of these resources, such as the exploration for oil and gas. Regions of geologically recent tectonic activity, such as earthquakes or volcanism, might be excluded in preference for older and more stable geologic terranes.

Host-Rock Specific Criteria: In countries where the types of different host rock types are limited, e.g., granitic gneisses of Scandinavia, very specific technical criteria can be developed. These criteria are highly quantitative. The geometry of a rock unit might be specified, such as the thickness of a geologic formation or the depth of disposal. One would expect to see specifications on the groundwater flow (very low hydraulic conductivity), groundwater chemistry (reducing conditions preferred over oxidizing conditions), and strong sorptive capacity (an abundance of sorbing minerals, such as clays, in the host rock).

Generic Criteria: In countries that can choose among a variety of geologic settings, rock-specific criteria become problematic; hence, generic criteria are preferred. Although difficult to quantify, statements of desired properties include, but are not limited to: (i) low hydraulic gradient and conductivity, (ii) thermal stability or high thermal conductivity; and (iii) high mechanical strength. Generic criteria can become exclusionary depending on how they are applied. As an example, a requirement of high thermal conductivity would favor salt over crystalline rock, or a requirement of high mechanical strength would favor crystalline rock over clay.

Equally important to the technical criteria are the social criteria. The U.S. NWTRB (2015) completed a historical analysis of 24 efforts to site a geologic repository in 10 countries. Only six of these programs remain on track. Nearly all of the programs reached a point of failure that required the programs to restart, e.g., Canada, with greater emphasis on the social aspects of siting a geologic repository. The profoundly important conclusion of this study is that successful siting requires not only a robust technical basis but also requires careful engagement and planning with local communities, indigenous peoples and states (Fig. 3).

Fig. 3 Selecting a site is an iterative process. There must be a schedule of successive evaluations of technical suitability and social acceptability defined prior to the process of selecting a site. Both activities must be coordinated with clearly defined decision points. Lighter shades denote early-stage judgments, and the darker shades denote later-stage judgments. Clearly, with the passage of time technical suitability and social acceptability must overlap in order to successfully site a repository—or they may diverge (NWTRB, 2015). Nuclear Waste Technical Review Board (2015)

Designing a Process for Selecting a Site for a Deep-Mined, Geologic Repository for High-Level Radioactive Waste and Spent Nuclear Fuel: Overview and Summary, pp. 51, Detailed Analysis, pages 228.

Safety

The safe disposal of radioactive waste in a geological repository depends on three physical and chemical processes:

- *Containment within the near-field* of the repository until radioactive decay has eliminated most of the inventory of radionuclides. Containment is accomplished mainly by engineered barriers, such as a durable waste form, a corrosion-resistant waste package or geochemical and hydrologic conditions that lead to the precipitation of radionuclide-bearing phases or their sorption onto corrosion products of the waste form and waste package.
- *Reduced concentrations of radionuclides in groundwater or on colloids.* This is facilitated by reducing geochemical conditions, sorption onto mineral surfaces along the transport path and dilution by groundwater.
- *Reduced mobility of radionuclides once released from the near-field to far-field geologic formations* such that radionuclide arrival at the biosphere takes a long time. Generally, this is insured by long-travel times for dissolved radionuclides and colloids in the groundwater.

These physical and chemical processes are evaluated in terms of an actual dose to a person or population within or at a specific time and location. This requires a knowledge of future population distributions and human activities, such as farming and irrigation practices with contaminated groundwater, near the area of the geologic repository over very extended periods. Hence, the key elements of regulations, discussed below, are an individual or group dose limit at a specific time and location into the far future.

Performance assessment models

The challenge in determining the safety of a geologic repository relies mainly on the projected results of models of the complex natural and engineered systems that are connected to biosphere models. These models cover large spatial and temporal scales from atomic-scale processes (e.g., corrosion of spent fuel) to global scale processes (e.g., climate change) that evaluate the physical and chemical processes that describe the release and transport of radionuclides to the biosphere. These physiochemical models are then coupled to biosphere models that evaluate exposure pathways for each of the radionuclides. Each radionuclide has a different chemistry, half-life, and radiotoxicity. This modeled behavior is projected over hundreds of thousands of years.

In the broadest sense, these models require: (i) a good knowledge of the source term, that is the radionuclide inventory and the amounts and speciation of the radionuclides. This inventory will change with time due to radioactive decay and the ingrowth of daughter product elements (e.g., the decay of short-lived ^{241}Am to long-lived ^{237}Np); (ii) the behavior of engineered materials in the repository environment; (iii) all relevant geophysical, geochemical and hydrological properties of the repository; (iv) the impact of radionuclide transport through geologic media until they enter the biosphere; and finally, (v) the exposure pathways to individuals or groups of people. This daunting task is made all the more challenging by the fact that over hundreds of thousands of years, the boundary conditions change. The composition and thermal output of the waste change due to radioactive decay. The hydrologic conditions may vary due to climate change or glaciation. The number and distribution of people and communities will be vastly different over time in the vicinity of the geologic repository. As an example of the complexity of such an approach, Grambow et al. (2014) and Grambow and Bretesché (2014) have illustrated the demands of going from long-term (years) experimental data to their use in a safety analysis applied to a geologic repository in clay over many hundreds of thousands of years.

Different countries have approached this challenge with different methods and strategies. In the United States, a total system, probabilistic analysis that was derived from methods to evaluate nuclear reactor safety is used (Ewing et al., 1999). The structure of the analysis is straightforward: (i) Identify numerical measures for the performance of the system. These metrics are usually a calculation of dose to a person or population over time at a specific location. This numerical measure is compared directly from the relevant national standards and regulations. (ii) Characterize the system. This includes all elements of the repository system, including waste form performance, radiochemical properties, geochemical conditions and the hydrology, to name a few; (iii) Create mathematical models of the system whose dependent variables are the performance measures for that system; (iv) Quantify uncertainties in the model relationships, and model parameters using probability distributions; (v) Propagate the uncertainty through the total system model in order to predict the uncertainty in performance measures; (vi) Compare the predicted performance measures to regulatory requirements. Although the process of completing a performance systems analysis (PSA) is straightforward in its description, in practice each step is a challenge. The PSA for the performance of the proposed repository at Yucca Mountain had thousands of input parameters, some represented by probability distributions or “look up” tables, and hundreds of subsystem models, many of which are coupled one to the other (Fig. 4). Perhaps, the greatest value to such an approach is that it helps the analyst understand how the different components of the repository strategy work. In the face of unknown futures, the analyst uses a variety of future scenarios to set the boundary conditions for the models in the analysis. In order to be “conservative,” bounding values of input parameters may be used or the scenarios may include the analysis of the consequences of extreme events such as volcanic eruptions, earthquakes or extreme changes in the climate.

Although such an approach has the appearance of being transparent and quantitative, there are many issues that can be raised when the complexity of the system is great and the uncertainty in the future boundary conditions and calculated performance measures are high. For the public and even for scientific reviewers, the total system analysis is opaque. Few will have the skills or time to examine all aspects of the analysis. Also, in such a complex analysis there are inevitable errors either in input parameters (e.g., solubility limits for radionuclides) or conceptual models (e.g., the relation between climate change and the infiltration rate of

Fig. 4 Schematic of model linkages used for the total system performance assessment of the proposed geologic repository at Yucca Mountain, Nevada. Figure from Swift PN (2018) Deep Geologic Disposal of Radioactive Waste at the Waste Isolation Pilot Plant and the Proposed Yucca Mountain Repository. In: *Presentation at Stanford University, After TRW Environmental Safety Systems (2000) Total system performance assessment for the site recommendation, TDR-WIS-PA-000001, Prepared for U.S. DOE, Las Vegas, Nevada, vol. 214, pp. 225.*

water). Research programs can correct errors with new data and understanding, but in the final analysis one must expect that there will be a gap between the modeled, projected behavior and the future, actual behavior of a repository.

There is also the important issue of the proper use and application of models (Oreskes et al., 1994; Saltelli et al., 2020) and a continuing effort to develop methods that can use expert opinion as part of the model construction (Kerr, 2020). The fundamental issue of whether quantitative model results can or should be used as the only criteria to determine compliance of a repository system remains a subject of debate (Blandford et al., 2011).

Safety case

Most European countries have taken a different approach from a fully quantitative analysis. They have developed the concept of a *safety case*. The phrase “safety case” is used in many different ways. In the most general sense, a safety case is (NEA, 2004).

“The synthesis of evidence, analyses and arguments that quantify and substantiate a claim that the repository will be safe after closure and beyond the time when active control of the facility can be relied on.”

A safety case is a blend of evidence that “quantif[ies] and substantiates” the argument for safety and draws on a wider variety of data. Quantitative analysis is certainly an important part of a safety case, but safety is also substantiated by other types of evidence such as observations of natural systems that demonstrate the behavior of key radionuclides in a natural and complex geologic settings (e.g., studies of the behavior or radionuclides at the Oklo natural reactors in Gabon or studies of the alteration and corrosion of native copper in geologic deposits, such as those found in upper peninsula of Michigan, United States).

The safety case is developed early in the site selection process and is derived from the regulatory framework. The safety case provides clear expectations for the role of the engineered and geologic barriers and how these barriers will interact with one another over time. As the site selection process narrows to a few sites and site characterization begins, the safety case is refined. If new knowledge of the site violates the original strategy for the safety case, then the site should be abandoned. The safety case can also be developed in a way that makes greatest use of quantitative models when the results are most useful, probably within the first hundred to thousands of years after repository closure. The quantitative analysis relies heavily on laboratory data that have a demonstrated relevance to the time scales being modeled. Qualitative evidence plays a more important role over geologic periods (e.g., the selection of a site that is in a stable craton far from active tectonic and volcanic activity). Observations of natural systems, so called natural analogue studies, can play a key role in evaluating the performance of a repository at more distant times (Côme and Chapman, 1987; Ewing and Jercinovic, 1987). Underground research laboratories can provide fundamental data, a conceptual understanding of coupled processes, and the opportunity to test operational plans under repository-like conditions (NWTRB, 2020).

In summary, the safety case is more like a compelling legal brief that marshals evidence from a variety of sources in order to make the case for safety (Ewing et al., 2018). Key to evaluating the efficacy of the safety case is the answer to the following questions:

- Has the implementer demonstrated a sufficient understanding of how the repository system will “work” over time?
- Have alternative conceptual models of the key processes been considered?
- Have the uncertainties in the quantitative and qualitative analyses been identified?
- Have key issues raised by affected parties, such as nearby communities, been addressed?
- Finally, and of great importance, is the safety case consistent with the early rationale for the original site selection?

Although the quantitative analysis of a calculated dose to a person at some distant time and place may be part of a safety case, the answers to the questions above are the compelling argument for safety.

Regulatory framework

Once the repository is designed and the effects of the physical and chemical processes on the multi-barrier system are understood, the total performance of the system of engineered and geologic barriers has to meet regulatory requirements (Ewing et al., 2016). There are various critical parameters that are measures of compliance. In the United States, early regulations limited the fractional release relative to the radionuclide inventory for the different engineered barriers at 1000 years after emplacement. For geologic barriers, the regulations on minimum travel times, as an example, were defined for the groundwater flow rate. However, these early regulatory requirements were considered to be too restrictive and led to suboptimal performance in the total system analysis; thus, subsystem requirements were replaced by a global risk-based calculation for the entire system. This risk-based approach requires a total PSA that probabilistically calculates a quantitative estimate of radiation dose to a person or population at a specific time and location. Typically, the regulatory period extends to a million years. And while the risk-based calculation of dose may be required by the regulation, the complexity of the biosphere adds to the uncertainty in the analysis of the global safety analysis.

Most countries extend their safety analysis to a compliance period of 1 million years. However, the level of the quantitative analysis varies (Ewing et al., 2016). For example, the Swedish KBS-3 concept intends to provide containment of the radionuclides within

the engineered barriers until the radioactivity level has decayed to that of the original uranium ore from which the waste was derived. Safety analyses may be based on quantitative determinative models early in the disposal period and then be replaced by more qualitative arguments for the rest of the period analyzed. In other words, the safety case approach uses different methods, quantitative and qualitative, as needed over the entire time of the safety assessment.

Another fundamental prospect in the regulatory framework is the location of the compliance boundary, defined as the point at which calculations are made for the level of exposure to the public. The compliance boundary can vary dramatically, even within a single country. At WIPP, the compliance boundary is a square, 4 miles on an edge around the centrally located repository. At Yucca Mountain, the compliance boundary is a rectangle, with its length parallel to the direction of groundwater movement, stretching to 20 km. This boundary is set to increase the effects of dilution and sorption processes along the transport path, effectively making the transport of radionuclides a part of the multi-barrier system. Undoubtedly, all of these assessments require some confidence in the knowledge of where people will live and their daily habits far into the future.

Public engagement and acceptance: The social filter

Even when the total performance of the engineered and geologic barriers meets the regulatory requirements and a regulatory agency declares a geologic repository to be safe, public acceptance remains key to success (Ewing et al., 2016). Public acceptance does not come at the end of the process, but rather is earned throughout the entire process from the initial site selection, site characterization, and through license approval (Ewing et al., 2016). In this regard, the experience in different countries has met with different levels of success (Metlay, 2016, 2021). Notably, there is one aspect of the technical strategy that contributes to a favorable communication with the public, and that is the simplicity of analysis on different repository strategies. A robust strategy based on simple principles that are transparent when communicating with the public and politicians is probably more useful than overly sophisticated, probabilistic analyses that are less transparent. In fact, every safety analysis requires both—a simple, compelling argument for safety, as well as an underlying scientific basis, which can be quantitative or qualitative (Ewing et al., 2016).

The basis for radionuclide migration in the environment

Introduction

In this article we will present some of the key processes that control radionuclide migration in a nuclear waste repository, from the nuclear waste matrix to the biosphere. These processes are known as near-field and far-field processes, in order to distinguish and categorize processes occurring at the vicinity of the waste package from the ones that control the fate of radionuclides in the geosphere.

The emphasis will be in high-level nuclear waste (HLNW) disposal, and mainly in crystalline rock environments, although we will introduce some of the key processes occurring in clay rock media, as an extension of the processes that control radionuclide migration in the clay buffer material surrounding the waste package. We will also touch upon the quantification of these radionuclide migration processes in the performance assessment of HLNW repositories.

Thermodynamic equilibrium vs. kinetic control

One key concept in the quantification of radionuclide migration is the concept of local thermodynamic equilibrium, which facilitates the systematic quantitative treatment of the chemical processes involved. Most of the chemical processes that we will hereto discuss can be treated as equilibrium processes, chiefly because the groundwater transport (or residence) times in the various parts of the repository are sufficiently long to grant this (Domenico and Schwartz, 1990; Bruno, 1997) (Fig. 1).

Nevertheless, there are two important exceptions to the equilibrium rule: dissolution-precipitation processes and redox reactions. In addition, some solid phase transformations shall be classified as kinetically controlled or as disequilibrium processes. This may include colloidal metastability given that it is an intrinsic disequilibrium process. We will try to discuss some of the implications as we get into the details of the process description. Radionuclide migration from the deep geological nuclear waste repositories to the biosphere will occur mainly by groundwater transport. In this context, radionuclides are only specific isotopes of some chemical elements and therefore their behavior in groundwater is controlled by the same aquatic chemical processes that control metal behavior in the various compartments of the environment. These processes are mainly (Stumm and Morgan, 1992):

- Aqueous complex formation
- Dissolution and precipitation of solid phases
- Redox transformations
- Colloid formation and stability
- Surface complexation/Ion exchange
- Surface precipitation
- Co-precipitation

A schematic of these processes om the context of deep geological disposal is presented in Fig. 2.

Characteristic vs. Residence times

Fig. 1 Characteristic reaction times vs. residence times of groundwaters in the deep geological disposal system. Adapted from Domenico PA and Schwartz FW (1990) *Physical and Chemical Hydrogeology*. John Wiley and Sons, and Bruno J (1997) *Trace element modelling*. In: Grenthe I, Puigdomenech I (eds.) *Modelling in Aquatic Chemistry*. Paris: OECD/NEA.

Fig. 2 Schematic view of the three kind of processes for the radionuclide migration in the deep geological disposal of nuclear wastes.

These processes can be classified as homogeneous and heterogeneous processes, depending on, if they occur in a single phase or if they involve phase transformation, including colloidal formation. Although the thermodynamic treatment of colloids as a phase is debatable.

Furthermore, some of the basic processes occur both in a single phase or through phase transformations, i.e., redox processes, therefore, is not very useful to handle them as homogenous or heterogeneous.

These basic aquatic chemical processes control radionuclide speciation and radionuclide distribution between the aqueous, solid, and surface phases. In terms of safety assessment are the solubility constant and the partition coefficient (K_d), two magnitudes that are fundamental in understanding and predicting radionuclide migration. However, radionuclide solubility and adsorption are dependent on the chemical speciation which at the end of the day is controlled by all the processes that we have presented.

Furthermore, the environmental impact of any metal, including radionuclides, is directly related to its bioavailability, which is in turn finally dependent on redox state and electrochemical behavior, and consequently on the radionuclide speciation. Furthermore, the link between the source of radionuclides (the waste) and the target biota occurs through groundwater transport processes, either advective or diffusive, or both, depending on the geological setting.

In the following sections will present a brief account of the basic aquatic chemical processes, with a specific focus on their relevance for radionuclide migration.

Aqueous complex formation

Complexes are stable entities that result from the formation of covalent bonds between a metal ion and the electron donating ligand.

Complex formation processes are the result of the interaction between ions and complexing ligands. Dissolved radionuclides are basically, metal and metalloids that form ions in water solution. These ions have a strong tendency to build complexes with the key complexing ligands present in the repository systems, including groundwater and in some cases, they also build ion pairs with counterions in concentrated media that may occur, for instance, in brines.

Their equilibria reactions are (in simplified form) written as:

And the equilibrium constants are defined as:

$$K_{\text{eq}} = [\text{RNL}]/[\text{RN}][\text{L}] \quad (2)$$

Ion pairs are the result of the electrostatic interaction in a critical distance which results in the total or partial neutralization of the ion charges. Longer-range electrostatic interactions are accounted for by the Specific Interaction Theory, which take into consideration the deviations from the pure Debye-Hückel electrostatic interactions. (The reader is referred to the publications by the NEA-TDB project for a more detailed explanation of these processes. [Grenthe et al. \(1997a\)](#) is an excellent introduction to aqueous chemical processes and in [Grenthe et al. \(1997b\)](#) there is a sound discussion of the effect of electrolyte theory on thermodynamic data.)

Dissolution and precipitation processes

These processes are extremely important in the evaluation of the safety of nuclear waste management options, including deep geological disposal. Dissolution is the key process controlling the release of radionuclides from the various nuclear waste matrices being disposed, while precipitation is a critical process to control the radionuclide behavior in the chemical gradients present in a repository system, particularly in the near field.

The thermodynamic treatment of the dissolution and precipitation processes is rather straightforward by using solubility constants such as:

Being the solubility constant defined as

$$K_{\text{so}} = [\text{A}] \cdot [\text{B}] \quad (4)$$

However, reality is far more complex. Nuclear waste matrices are by definition complex multicomponent systems. For instance, despite that the composition of spent nuclear fuel is up to 95% $\text{UO}_2(\text{s})$, its radionuclide content is present in several phases within or outside the uranium dioxide matrix. Thus, when dealing with spent nuclear fuel solubility and the subsequent radionuclide release, a complex multiphase approach must be applied. We will further address this when discussing near field processes.

Likewise, the reverse process, radionuclide precipitation, is also a remarkably complex process. While it could be argued that the solubility constant (Eq. 4) applies to determine the solubility limit of a certain radionuclide in the near field and the far field environment, the reality is richer and far more complex.

The fact is that radionuclides in the repository environment are normally trace components, and consequently their solubility behavior is determined by the interactions with the main groundwater components through their migration pathway. This means that in a very few cases, the individual solubility of a radionuclide is a relevant parameter to understand its migration behavior. As a matter of fact, the interaction between many of the key components of the repository system with groundwater is controlled by solid solution-aqueous solution processes, particularly in the near-field, but also in the far field.

Many components in UO_2 and MOX spent nuclear fuel are present as solid solutions of the UO_2 matrix, and their dissolution behavior can be explained by using the framework of aqueous solution-solid solution processes ([Bruno et al., 2007](#)). A similar situation has been described for the behavior of trace components in the altered layer of vitrified nuclear wastes ([Grambow and Müller, 2001](#)), the alternative matrix for the closed fuel cycle.

Cement is a central component in many designs. Its alteration forms an array of calcium silicate hydrate solid solution phases, commonly known as CSH.

The corrosion of steel containers and cast iron inlets produces a variety of Fe(III)/Fe(II) oxyhydroxide solid phases that are able to incorporate trace components in their structures. While initially the trace metal interactions are mainly controlled by adsorption processes and described by surface complexation models (Dzombak and Morel, 1990), the evolution of these Fe(III) oxyhydroxide phases with time (aging) and their interactions with contacting fluids may be described also in the context of the aqueous-solid solution systems (Bruno et al., 2007).

We will discuss these processes in more detail as we describe radionuclide migration in the near field and far field environments.

Redox processes

In principle, radionuclide migration occurs through different environmental compartments with a varying degree of oxidation. One of the key safety principles for many high-level nuclear waste repositories is based on the fact that the waste itself and containment system, known altogether as near-field, is kept under reducing conditions. The grounds for this is that deep underground the redox condition varies from anoxic to reducing.

In their migration pathway towards the biosphere, radionuclides will encounter various stages of the redox scale (Stumm and Morgan, 1992) which will have an impact on their chemical speciation, solubility and surface distribution (adsorption). Therefore, the redox state constitutes together with the pH, the two master variables that control radionuclide migration in groundwater systems.

Redox reactions are the result of electron transfer processes from the reduced species to the oxidized one, and vice versa. Contrary to the proton, the free electron is not stable in aqueous solution. Hence, redox reactions are the result of, at least, two simultaneous redox pairs. This brings some additional complexity to the definition of redox systems, mainly because there are important kinetic hindrances that make these reactions to be slow in natural systems. In addition, as we have already discussed, redox processes may occur in a single aqueous phase but also through phase transformation reactions.

However, as explained in Bruno (1997), for most of homogeneous redox reactions equilibrium can be assumed to be reached within the long groundwater residence times expected in the repository system. The exceptions to this principle are the redox reactions involving multielectron transfer and large structural rearrangements, for instance, the reduction of sulfate to sulfide, which is a slow process, unless it is mediated by bacteria.

This brings us to a very important issue when dealing with redox process: living organisms thrive in the energy gradients generated by these redox reactions and therefore they play a critical role defining the biogeochemistry of subsurface systems. Therefore, microbial mediated reactions can play a very relevant role, even in deep groundwater systems (Hallbeck and Pedersen, 2008).

There is a number of relevant processes for radionuclide migration that occur at the frontier of the solid solution interface, these include colloid formation, surface complexation and surface precipitation. We will touch upon them in the following sections.

Colloid formation

This is a critical process for radionuclide migration. Colloids are nanoparticles of size between 1 and 1000 nm of organic or inorganic composition which are found in natural groundwaters (Stumm and Morgan, 1992), and particularly in anthropogenically disturbed systems, such as nuclear waste repositories (McCarthy and Zachara, 1989; Kim, 1991; McCarthy and Degueldre, 1993).

Colloids have been classified as intrinsic (*eigen*) colloids, or pseudo-colloids. Intrinsic colloids are formed by many metal ions when they hydrolyse and particularly by the actinide ions. Actinide (IV) are very prone to build colloids in water systems.

Pseudo-colloids are basically radionuclides attached to external colloidal phases occurring in the various compartments of the repository system. This nomenclature is somewhat misleading, as pseudo-colloids are as real and normally even more critical to radionuclide migration than *eigen*-colloids.

The main process involved in colloid-driven transport is surface complexation and/or surface precipitation. These processes are normally bumped in the general term "adsorption," which includes all reactions responsible for the attachment and immobilization of radionuclides on solid (mineral) surfaces.

Adsorption is a very important process in the safety assessment methodologies used in nuclear waste management, but its handling lacks at present the thermodynamic rigor granted for other migration/retardation processes. We will discuss this point deeply in the performance assessment section.

Transport processes

As we have already indicated, the main mechanism for the migration of radionuclides is groundwater transport. Gas transport may also occur, particularly for gaseous nuclides like Rn, but it has a minor contribution to the overall radionuclide migration process in the HLNW context.

The main hydrogeological mechanisms for groundwater transport are advection and diffusion.

Advection is the process in which the migrating radionuclides are transported at the rate of the flowing groundwater. In crystalline rock systems, advection occurs through fractures and microfractures, where it combines with diffusion processes. Radionuclide transport through advection is mathematically approached by using the mass and energy conservation laws.

Diffusion is the net movement of radionuclides in concentration gradients and it is the main operating mechanism for radionuclide transport in geological media with very low permeability like clay rocks, including the bentonite buffer material. A specific case of diffusion applies to the mechanism operating in bulk rocks at the interface with conductive fractures, which is known as matrix diffusion (Neretnieks, 1980).

Diffusion is mathematically approached by Fick's law although some relevant diffusive transport processes are considered not to follow this law and are considered *non-fickian*.

In general, advective transport is faster than diffusive transport, and therefore it is more efficient in terms of radionuclide migration.

Diffusive transport is the main groundwater transport process in clay rock environments which is the preferred geological disposal option for HLW in countries like France, Belgium and Switzerland, for instance.

Reactive transport models

The integration of chemical and groundwater transport processes affecting radionuclide migration is conducted by applying reactive transport models. These models are fundamental for assessing the potential radionuclide mobility in the various portions of the repository system and are the basis of most safety assessment exercises.

A large part of the development of these models have been the result of the work related to the needs of development of these kind of models as a result of the progression of safety assessment exercises for the geological disposal of HLNW.

This is clearly proved/shown by comparing two of the seminal works concerning Reactive Transport Modeling, which have been collected in the Reviews of Mineralogy and Geochemistry (Lichtner et al., 1996; Steefel, 2019). While in the 1996 version (Lichtner et al., 1996) the emphasis was in the application of these models to the understanding of the evolution of geochemical systems, the issue from 2019 (Steefel, 2019) contains many references to nuclear waste management problems in spite of the fact of the somewhat parochial sight from US scientists which tend to overlook what is being done in Europe and elsewhere which in many respects is far more advanced in the applicability of these models for nuclear waste management (Markelova et al., 2020).

However, in a recent review, Steefel (2019) points out that one of the key limitations of the applicability of Reactive Transport Models is the insufficient approach to multicomponent sorption that the K_d parametrization offers. Something that we consider also to be a weakness in the consistent application of Reactive Transport Models in the safety assessment of nuclear waste repositories.

There is a substantial bibliography concerning reactive transport models, and the reader is referred to these works for additional information. An overview of the historical development of Reactive Transport Models is given in the following picture extracted from a recent report written by Amphos 21 concerning the development of Reactive Transport Models in fractured crystalline media (Markelova et al., 2020) (Fig. 3).

Fig. 3 Historical development of Reactive Transport Models in crystalline, fractured, rock (Markelova et al., 2020).

Nevertheless, the fundamental question remains the same: following the GiGo dilemma, the outcome of these models will only be as good as the input data. If we insist on providing limited chemical information into these models, the output of these models will still be rather limited, no matter how sophisticated the hydrological model is.

Geological disposal of high-level nuclear waste (HLW)

Near field components and processes

As it has been mentioned in the Introduction, the environment surrounding a nuclear waste repository is divided in two main zones, the near and the far field. The near field is the closest area surrounding the waste emplacement and it is by definition affected by the presence of the waste.

In principle, the far field is not disturbed by the waste emplacement, although there can be a transition zone which is indeed perturbed by the placement of the waste.

In terms of radionuclide migration, the near field is a complex system where radionuclide release processes are originated, and where the released radionuclides interact with a number of engineered barriers. This is prior to their continued travel in the bedrock in which the repository is located which constitutes the far field.

The near field of a nuclear waste repository is mainly composed by the waste matrices and their containment which may vary depending on the type of waste which not only depends on the activity but also on the preferred nuclear cycle type, open or close.

Nuclear wastes are classified according to their radiological activity and the decay times of the radioisotopes included in the waste.

For low and intermediate waste, the near field can be a heterogenous mixture of containment materials and waste packages, depending on their origin. A typical example of low and intermediate nuclear waste repository is given in Fig. 4.

Typically, many L + IW waste streams coming from the nuclear power stations are conditioned in concrete and steel containers. In addition, there are some waste streams, particularly arising from former operations, that have been conditioned in bitumen.

HLW streams are diverse but the majority can be classified either as spent nuclear fuel (UO₂-fuel or MOX) or vitrified HLW, in which the waste arising from the reprocessing activities is mixed in melt-glass prior deposition.

Hence, radionuclide migration in the near field is a complex multi-process array which has many intricacies depending on the management concept. We will try to categorize these, depending on the waste type and the disposal concept.

Near field processes in high level nuclear waste (HLW) disposal

As we have previously indicated, there are two main streams of HLW, spent nuclear fuel and HLNW glasses. In both cases, the initial process that destabilizes these waste matrices is their contact with groundwater and the subsequent radionuclide release.

Fig. 4 Layout of the SFR—SKB's Final Repository for Short-Lived Radioactive Waste located at Forsmark in the municipality of Östhammar, Sweden.

The intruding groundwater has gone, in principle, through the various components of the near field, prior to contacting the waste matrix. Therefore, the interactions of groundwater with the near field components are critical to radionuclide release, as well as to radionuclide migration.

In the case of spent nuclear fuel, the waste is surrounded by the zircaloy cladding, a metallic container, and the buffer material. In the following Fig. 5 we present a scheme of the KBS-3 concept for UO_2 spent nuclear disposal that is being implemented in Sweden and Finland. In this case, the metallic container is a copper canister with a ductile iron insert and the buffer material is compacted bentonite clay.

Thus, the key processes that will render possible spent fuel dissolution are the interaction of groundwater with the surrounding bentonite, and the corrosion of the copper canister. If the groundwater corrodes the copper canister, then it will get in contact with the iron inlet. This results in hydrogen generation and the development of highly reducing redox conditions (Duro et al., 2014). This process is also key in controlling the redox condition of the low and intermediate waste repositories, where most of the waste materials are kept in iron containers.

The development of hydrogen in the vicinity of the spent fuel has many implications in the dissolution of spent nuclear fuel and the subsequent radionuclide release (Carbol et al., 2009), imposing reducing conditions at the spent fuel surface, which counterbalances the production of oxidants by water radiolysis.

In any case, several radionuclides will be released from the disposed spent nuclear fuel if they are put in contact with groundwater. These are mainly fission products and are categorized as the Instant Release Fraction. The Instant Release Fraction (IRF) is the fraction of the radioactive inventory that will be released from the waste “immediately” after the fuel rod cladding fails, and the waste containment is compromised.

The waste form consists in a rod containing stacked pellets of polycrystalline UO_2 fuel during reactor operation, concentration and thermal gradients drive redistribution of some of the fission products from intragranular to the intergranular space, and outside the pellet towards the inner-rod void space. It is generally assumed that under repository conditions, breaching of the cladding would rapidly release the inventory accumulated in the void space of the rod. In addition, the radionuclides segregated at the fuel grain boundaries would also be released relatively quickly.

After the instant release of radionuclides from the fuel, a much slower radionuclide release mechanism would occur over long periods of time due to dissolution of the UO_2 matrix (Bruno et al., 1996; Poinssot et al., 2005). The main alteration reactions that may occur at the spent fuel/iron canister/groundwater interface were described as a result of an Euratom collaborative project (Poinssot et al., 2005) and have been depicted in the following Fig. 6.

It is important to realize that the schematic shown in Fig. 6 is not drawn at scale. The oxidizing front extends to some hundred microns from the surface at maximum, while the reducing front covers some decimeters in range. The near field rock, which is placed at meters length and separated from the canister by the backfill, ensures that the overall redox condition remains reducing. The net effect is that H_2 generation at the reducing front is able to offset the surface oxidation (Carbol et al., 2009).

Once radionuclides are released, they encounter a changing groundwater composition and some of the initially released radionuclides, particularly the actinides, will meet reducing conditions which will favor their precipitation as actinide(IV) hydroxides. In the case of Pu, it may trigger the build-up of eigen-colloids, as we have previously discussed.

Fig. 5 The KBS-3 concept for spent nuclear fuel disposal (SKB, 2020).

Fig. 6 Scheme of the reactions occurring at the near field of a spent nuclear fuel repository (Ewing, 2015).

In the case of other relevant radionuclides like radium, their migration will be controlled by processes affecting the solubility of barium. The presence of sulfate in the contacting groundwaters will facilitate the precipitation of the insoluble barium sulfate (barite), and radium will co-precipitate with the barite that is formed. There has been a substantial amount of research (i.e., Vinograd et al., 2013) of this co-precipitation process since its consideration in performance assessment models (Grandia et al., 2008).

Further to these chemical processes, the migrating radionuclides will encounter the metallic components, including the zircaloy cladding and the components of the canister, basically metallic iron and copper, in the case of KBS-3 concept. Under the anaerobic conditions expected in the near field, iron will be corroded to magnetite (Duro et al., 2014) and therefore radionuclides will interact with the magnetite surface.

The interaction of radionuclides with the surface of magnetite has been investigated, particularly for redox sensitive elements like uranium (Missana et al., 2003a,b; Singer et al., 2012) and selenium (Martínez et al., 2006); but also, non-redox sensitive elements like Th (Rojo et al., 2009).

An additional component that is not depicted in Fig. 6 is the buffer material surrounding the canister, which has several functions, mainly to guarantee physical and hydrological stability. In the KBS-3 concept, the selected buffer material is compacted bentonite, which is mainly composed by montmorillonite clay (> 80%). It also contains a few accessory minerals like feldspars, quartz, cristobalite, gypsum, calcite, and pyrite. Montmorillonite belongs to the smectite group, in which all the minerals have an articulated layer structure. A model structure of bentonite is given in Fig. 7.

The physico-chemical properties of bentonite have a strong influence in the migration processes that may occur within the bentonite barrier. Water saturated bentonite has an extremely low hydraulic conductivity and therefore radionuclide migration is diffusion controlled and the predominant retention process is sorption, either through ion-exchange and/or surface complexation processes.

Montmorillonite consists of octahedral alumina sheets sandwiched between tetrahedral silica sheets (2:1 clay). These clay minerals feature two distinctly different types of surface, where two main types of sorption take place (Stumm, 1992):

- The siloxane ("layer") surfaces of clay minerals are permanently charged surfaces. These charges derive from isomorphous substitutions, which result in a constant negative surface charge. This charge is partly compensated by cations and bound to the clay surface, and partly by cations simply accumulated in a counter-ion swarm. The latter is equivalent to an electrical double layer extending from the surface. Macroscopically, sorption takes place when compensating ions are exchanged therefore ion exchange models of the site-binding type have are used to describe this process.
- The edge surfaces of clay minerals are variably charged surfaces. They carry a net positive or negative surface charge depending on the sorbed species to their surfaces which often involve surface-bound OH⁻ groups. Surface complexation and ligand exchange models were established by Stumm, Schindler and co-workers in the 1970s by extending proton binding and metal coordination chemistry in a rigorous fashion to surface chemistry. To account for the electrostatic field, the mass laws for surface equilibria, often include an electrostatic correction term. These corrections are based on the Electrical Double Layer (EDL) theory (Stumm, 1992).

In terms of the interaction with migrating radionuclides, ion exchange is the main sorption mechanism for alkali, and alkaline-earth elements, as well as for some transition metals at low pH values, where positive species are predominant. In the pH range of interest, surface complexation is generally the relevant process for all the key radionuclides (transition metals, actinides, lanthanides, and key groundwater anions such as carbonate).

It is important to realize that both ion exchange and surface complexation reactions take place simultaneously, but at different surface locations. The most important factor for both processes is the ion content of the porewater, which is principally determined by the original cations in the exchange positions of the montmorillonite, the readily soluble minerals in the original bentonite material, like calcite, and by the influence of the intruding groundwater.

Protons are bound to the edge sites of clays (as well as to ion exchange positions at very low pH), which means that pH changes can occur due to surface chemical reactions. Given its buffering properties, the montmorillonite can counteract external changes in pH. The presence of pyrite as an impurity has also an effect as redox buffer (Wanner et al., 1992).

Fig. 7 Layered silicate structure of montmorillonite, the main component of bentonite (Karnland et al., 2006).

In terms of describing radionuclide migration through bentonite, the reversibility of the sorption is a fundamental concept. Ion exchange and surface complexation models have been developed to take into consideration radionuclide sorption in bentonite. The most comprehensive and systematic work in this context has been performed by the PSI group, led by Mike Bradbury and Bert Baeyens. There are a series of publications that establish consistent and reproducible surface complexation models to describe the interaction of most radionuclides with bentonite (Bradbury and Baeyens, 2009).

One specific complication of the radionuclide interaction with bentonite is the concept of anion exclusion. As we have already discussed, the montmorillonite structure has an excess of negative charge that is compensated by cations in the interlayer space and on the outer surface. Anions are therefore, repelled from the negative surface of montmorillonite and thus, occupy only part of the pore space of bentonite. This effect can become small, or even insignificant, when the bentonite is highly compacted and the external solution has low ionic strength (Molera et al., 2003; Muurinen et al., 2007; Van Loon et al., 2007). The reader is referred to these publications as well as to the work of Tournassat and Appello (2011).

Another aspect that is fundamental in terms of radionuclide migration is the fact that compacted clays in general, and bentonite in particular, are very efficient filters for colloidal transport and microbial development (Holmboe et al., 2010; Haydn et al., 2018), this in some respect helps to constrain the effect of microbes and colloids on radionuclide transport through the buffer barrier as well as in clay rock in general.

There is, however, a complication in this context, which is that bentonite colloids can be generated as a consequence of ground-water weathering under certain circumstances (Missana et al., 2003a,b). This is particularly important when diluted groundwater will enter in contact with the bentonite buffer material. In principle, this is a process that is unlikely to happen in contact with groundwater as its cation content is sufficiently high to prevent it, but it might be possible if very diluted melt waters intrude the repository in glaciation/deglaciation cycles. This phenomenon has been largely investigated within nuclear waste management projects located in areas where glaciation/deglaciation cycles are likely to occur through the forthcoming glaciation cycles, like the Swedish, Finnish and Canadian programmes.

Radionuclide migration in the far-field

Most of the processes that we have discussed in the near field are reproduced with a different intensity in the far field. In clay rock repositories the key processes we have established for the bentonite buffer material are acting on the migration of radionuclides. Ion-exchange and sorption are the key chemical retention mechanisms, while diffusive transport is the predominant transport pattern.

In crystalline rock repositories, radionuclide migration occurs through fractures and the transport patterns are mainly advective, although diffusive transport within the rock matrix plays a substantial retention role. Radionuclide migration processes are very dependent on their chemical speciation and therefore the aqueous composition of the flowing groundwater will determine most of the retention processes through the far field.

Groundwater chemistry is mainly determined by the type of rock. Granitic groundwaters have a quite constant composition mainly controlled by the dissolution and precipitation of calcite and feldspars in the fractures. The master variables of the system are pH and pE (redox potential). While pH is rather constant in undisturbed groundwaters, the redox potential varies depending mainly on depth and the potential intrusion of oxygen from the atmosphere.

As a rule, deep groundwaters are reducing while surface waters are oxidic. This clearly determines the chemical speciation of the redox sensitive radionuclides, like Uranium, Neptunium and Plutonium, and consequently drives their sorption interactions.

Aqueous complexation influences the radionuclide sorption behavior, both by stabilizing the radionuclides in the aqueous phase and increasing their surface complexation. An example is given in the study by Bargar et al. (1999), in which surface complexation of bidentate carbonate complexes increases uranium sorption. This is one of the main reasons while aqueous-surface equilibrium models are useful to ascertain these processes, which would be largely overlooked if the K_d approach would be considered.

The salinity of the groundwater also affects the extent of ion-exchange in clay materials, as solutes will compete with the radionuclides for ion-exchange sites. This is particularly important in bentonite, in which ionic strength has a strong effect on pore water composition, but also in the clay rock as well as the clay materials coating the fracture surfaces.

Sorption can take place directly on the outer surfaces of flow-bearing fractures or on grain-boundary surfaces and microfractures within the rock matrix, where the porewater is effectively stagnant. This is the basis of the phenomenon conceptualized as Matrix Diffusion (Neretnieks, 1980).

Radionuclide sorption can also take place on other materials, such as secondary clay minerals in fracture-surface coatings. As a rule, sorption processes result in the retardation of solute transport along a flow path. However, if radionuclides are attached to colloids, then radionuclide migration will not be retarded. Sorption is only the first step towards phase transformations, such as precipitation and co-precipitation, which can give rise to additional radionuclide retardation.

Radionuclide precipitation/dissolution processes and the formation of solid solutions (i.e., coprecipitates) is crucial for establishing relevant background concentration ranges for stable and naturally occurring radioactive isotopes, which can influence the sorption of the radioactive isotopes (the radionuclides), which are originated in the repository (SKB, 2014). This is particularly important for elements such as cesium, strontium and uranium.

Natural background levels of radium are sufficiently high to determine the concentration range in which radium adsorption must be determined. Co-precipitation of radium and barium as a solid solution in barite is a well-known process, and under

most groundwater conditions is expected to exert an important control on the concentration range of radium present in groundwater owing to the low solubility of barite and its ubiquitous nature (Bruno et al., 2007).

The different minerals participating in sorption reactions have different capacities for adsorption. Clay minerals and iron oxyhydroxides, for example, have a large sorption capacity, whereas quartz and feldspar tend to sorb very weakly. In granitic rocks, biotite, or its alteration product chlorite, as well as hornblende, have the strongest sorption affinity for radionuclides. The sorption of cesium and strontium, for example, is known to be strongly concentrated to biotite and chlorite (micas) which, being phyllosilicate minerals, have a large capacity for ion-exchange sorption (e.g., Torstenfelt et al., 1982; Huitti et al., 1998).

Uranium and neptunium also have an affinity for the iron-rich minerals (Kienzler et al., 2009), possibly due to surface complexation sorption on frayed edge sites of micas combined with reduction to the more strongly adsorbing tetravalent state. The surface complexation sorption of nickel, plutonium, and americium, on the other hand, appears to be less specific.

Although sorption of solutes, including radionuclides, is generally reversible in a thermodynamic sense, the incorporation of metal ions into solid phase lattices can result in an effectively irreversible immobilization. However, owing to the dynamic equilibrium of most common mineral phases likely to incorporate radionuclides, irreversible immobilization is not always verifiable, and such retardation processes are usually neglected in safety assessments. This is of course a weak argument difficult to defend because the irreversibility of some of these processes may involve the formation of "radionuclide pumps," which are accumulated in some fracture zones and may be released when the chemical conditions are suddenly changed, for instance, through tunnel excavation and fracture grouting.

Although the master variables pH, redox, and concentration of complexing ligands in the groundwater largely determine the speciation (distribution of an element among different chemical species) of chemical elements, temperature and pressure also play a minor role given the effect that these variables can have upon the thermodynamics of chemical reactions. The importance of chemical speciation in safety assessments lies in its impact on the geochemical retention and immobilization reactions likely to occur, and their consequences for radionuclide mobility.

The existence of an alkaline pH plume as a result of the use of concrete in various parts of the repository may influence the retardation of radionuclide transport in a number of ways. This is particularly important in low and intermediate waste repositories where most of the waste is conditioned in concrete.

The penetration of an alkaline plume will affect the migration of radionuclides in several ways, either by increasing the solubility of some key actinides and lanthanides, which tend to be more soluble at high pH values due to the formation of anionic hydrolysis complexes, but also affecting the rock and their fracture materials and therefore disturbing the retardation properties.

The alkaline plume may influence retardation of migrating radionuclides by altering the material properties of the rock matrix. In the immediate vicinity of the repository, high pH conditions may promote the dissolution of quartz and precipitation of secondary Ca-silicate crystalline or gel phases. Similarly, the dissolution of plagioclase may result in the precipitation of Mg-saponites. Since these secondary minerals typically have a larger molar volume than the primary quartz dissolved from the rock matrix, the net effect is a decrease in porosity, both in the rock matrix and in the fractures, which will be shotcreted.

Although this is an effect which might primarily influence the rock matrix effective diffusivity, it may also influence adsorption, as secondary precipitates would cover the surface of other minerals in such a way that the overall retardation effect would be altered. The net effect of the alkaline plume in fractures will change with time as the alkalinity of the cement-based plume will decrease with time as the cement ages and alkaline cations are depleted.

Natural analogs

In any case, the heterogeneity and complexity of all the migration processes involved in a HLNW repository, together with the fact that these processes have to be assessed for hundredths of thousands of years, has promoted the use of Natural Analog systems as a way of assessing the validity of the key hypothesis and their quantification.

What follows is a brief account of the use of Natural Analog studies in radionuclide migration investigations related to HLNW disposal. For a more detailed account the reader is referred to Duro and Bruno (2012).

Generally speaking, Natural Analog studies have helped to increase the confidence in the qualification and quantification of the key processes that control radionuclide migration. It has also given the possibility to test the Hydrogeochemical Models used to describe radionuclide migration in a repository system. This has been the combination of several testing exercises of these models in Natural Analog systems, which have provided confidence on the tools, but also have helped to improve the thermodynamic data bases associated to these calculational tools.

The key NA studies that were used for this purpose are the following, classified based on the geological media involved:

1. Crystalline media
 - a. El Berrocal (Spain)
 - b. Palmottu (Finland)
2. Sandstone-clay media
 - a. Oklo (Gabon)
 - b. Cigar Lake (Canada)
3. Alkaline-volcanic media
 - a. Poços de Caldas

4. Hyperalkaline media
 - a. Maqarin (Jordan)

A description of these analog systems can be found in [Miller et al., \(2000\)](#), and the main outcome of these studies has been published in [Bruno et al. \(2002\)](#). Additionally, Natural Analogs studies are also used in the Safety Assessment of HLNW repository to bound the key processes involved in radionuclide migration and the models used for their quantification.

Radionuclide migration in safety assessment exercises

The space and time scales involved in the safety assessment of HLNW repositories impose many constraints in the way the radionuclide migration processes we have previously described are handled. This is in spite of the continuous improvement and the enlargement of the computing capacity.

As a matter of fact, the handling of radionuclide migration processes in safety calculations simplifies in a dramatic way the complexity we have been discussing. Two main chemical processes are integrated in these calculations:

1. Radionuclide solubility, to determine the source term from the waste form;
2. Radionuclide sorption, to describe the interactions between radionuclides and the contacting surfaces through the migration pathway.

Furthermore, several simplifications are involved in the interactions that are considered in the migration pathway. For instance, in the case of spent nuclear fuel disposal, the zircaloy cladding is/is considered as transparent in terms of radionuclide migration. This is a hypothesis which can be absurd, as in the reverse it would imply that the radionuclides generated and contained in the fuel matrix would be released freely in the operating reactors.

When it comes to the metallic containers, they are only treated as physical barriers and this applies exclusively to the integrity of the copper canister for which corrosion mechanisms under repository conditions have been extensively investigated ([Hedin et al., 2018](#)).

The role of iron and its corrosion products as a radionuclide retention barrier is largely overlooked based on a pessimistic approximation to the consequences of radionuclide migration. Hence an enormous retention capacity is not considered in HLNW repositories but also in LINW ones, where iron, together with cement, are the main system components.

Finally, the complexity of radionuclide sorption in the various parts of the repository is dumped in partition coefficients, which cannot represent the richness of the surface interactions in a complete manner, and cannot be linked properly to the geochemical variability of the system. Additionally, linear K_d cannot represent properly the competitive effects on sorption among the various radionuclides ([Steeffel, 2019](#)).

The main reason for this can no longer be the lack of computing capacity in a time where fully coupled models are now run routinely (see the “Reactive transport models” section). The main reason behind this is the fact that the complexity of the hydro-geological models hijacks the capacity of transport models to capture the richness (and the beauty) of radionuclide migration chemistry.

Let's hope that in the future the chemical processes behind radionuclide migration will be fully integrated in the radionuclide transport models used for the safety assessment of HLNW repositories, and that the chemical complexity of the repository components is considered in a comprehensive way.

Probably, the transition from conceptual to real repositories will require a more detailed quantitative account of these processes, both in the near and the far fields, as construction and operation of the repository will alter the migration pathways and in some cases in an irreversible manner. In these cases, the hypothesis of linear K_d to represent radionuclide sorption will become less and less defensible.

Presentation of the sole geological repository in operation: The WIPP Site (US)

The United States is the first country in the world to have begun operating a deep geological repository for radioactive waste. The Waste Isolation Pilot Plant (WIPP) in Carlsbad, south-eastern New Mexico, is currently the only waste disposal facility of its type in existence. This site for the disposal of defense-related transuranic waste (TRU) in a deep salt layer was commissioned in 1999 (Fig. 1).

Defense-related TRU waste is so called because it is made up of materials that have been contaminated with plutonium. It partly consists of protective clothing, such as coveralls, gloves, shoe covers, etc. It also includes dismantled machine tools, rubble from the demolition of workshops and sludge contaminated with radioactive substances from US nuclear weapon plants.

Under the 1992 Land Withdrawal Act, WIPP is not licensed to accept high-level waste or spent fuel from civilian nuclear activity initially destined for disposal at the Yucca Mountain repository in the Nevada desert.

WIPP is located in a sparsely populated desert area. Waste is disposed of in salt domes. The salt formations, the top of which lies 305 m below the surface, are 650 m thick. Salt is considered to be a good medium for repositories as it is free from water. The geology of the salt formations at the WIPP has been stable for 200 million years. The choice of salt formation for WIPP is justified by the absence of freshwater, the ease with which this material can be excavated, its non-permeability and its geological stability. However, its most important quality for the purpose of radioactive waste containment over a very long time scale is the way in which the saline formation seals all fractures and naturally closes all openings (US DOE, 2016) (Fig. 2).

The underground repository facilities are laid out on a plane at a depth of approximately 650 m. They comprise four shafts: two air intake and extraction shafts, one for mining activities and taking salt to the surface, and one for lowering and managing waste. The site is organized into 10 waste disposal areas (Fig. 3).

Fig. 1 WIPP surface facilities. U.S. Department of Energy.

Fig. 2 WIPP geological stratigraphic sequence. U.S. Department of Energy.

Fig. 3 WIPP site architecture. U.S. Department of Energy.

Fig. 4 Disposal of contact handled TRU waste. U.S. Department of Energy.

Two handling methods are used depending on the level of radioactivity of the waste packages concerned. If the gamma emission rate is high, the waste is put in place using a remote handling system. If the rate is low, contact handling may be used (Figs. 4 and 5).

The TRU waste with the highest level of radioactivity requires remote handling. Special-purpose Horizontal Emplacement and Retrieval Equipment (HERE) is used to push packages into disposal cells excavated into the walls of a disposal cavern (Fig. 6).

The Department of Energy (DOE), which operates the facility, is licensed to dispose of up to 173,600 m³ of TRU waste from National Defence-related activities. Operation is planned to continue until 2070. The National Defence argument undoubtedly played a role in overcoming the many procedural barriers that had to be passed before the site could open. Twenty years passed (1979–99) between the initial license for WIPP being granted by Congress and the final operating license being issued by the New Mexico Environment Department.

By the end of 2005, after 6 years of operation, the site was 20% full, with no releases of radioactivity into the environment or any worker contamination. However, operation was interrupted in February 2014 following two events that took place within the space of 10 days:

- 5 February: An underground fire on the engine of a transport vehicle led to many operators being evacuated due to intoxication by smoke inhalation.
- 14 February: Radioactive contamination detected at the surface of the site near the air exhaust at levels that do not pose a risk to the public and the environment. This contamination resulted from an exothermic reaction due to chemical incompatibility between an organic absorbent material introduced into a drum and its contents, a radioactive nitrate salt.

Fig. 5 Disposal of remote handled TRU waste. U.S. Department of Energy.

Fig. 6 Conceptual view of the WIPP architecture including the new ventilation shaft. U.S. Department of Energy.

The operations to dispose of transuranic waste, produced by defense-related activities, have gradually resumed since the end of 2016. Adopting a phased approach, the return to operation is described in the WIPP Recovery Plan, published by the DOE at the end of September 2014. In 2019, the US DOE published a four-year strategic plan for the WIPP, including the construction of a fifth ventilation shaft with a rate of air intake from the surface of 900,000 m³/h, in addition to the existing shaft which has a rate of 290,000 m³/h. The construction contract was formalized in August 2019 by the U.S. Department of Energy (DOE) Carlsbad Field Office (CBFO)—(US DOE, 2019).

Summary of the Swedish and Finnish granite repository project

Sweden

The four electricity companies that operate Swedish nuclear reactors—Vattenfall, Forsmarks Kraftgrupp AB, OKG Aktiebolag and E.ON Kärnkraft Sverige AB—created the Swedish Nuclear Fuel and Waste Management Company, SKB, to meet their current and future obligations regarding radioactive waste. SKB is responsible for the handling, transport and disposal of all spent fuel and nuclear waste produced by nuclear power plants and operates the facilities at the back end of the nuclear fuel cycle, which are concerned with the storage of spent fuel.

Principle of the repository

Since work began on the Swedish final repository project in the late 1970s, SKB has defined a number of principles for the design of the final repository. These principles constitute the safety doctrine defining the KBS-3 concept (SKB, 2015). They are summarized below.

- By building the repository deep underground in a geological environment that is stable in the long term, the waste is isolated from the human environment. This means that the repository is not strongly affected by societal changes or the direct long-term effects of climate change taking place at ground level.
- By locating the repository on a site where it can be presumed that the host rock is of no economic interest to future generations, the risk of human intrusion is reduced.
- The spent fuel is surrounded by several natural safety barriers that have been designed.
- The main safety function of the barriers is to contain the fuel in a tank.
- In the event of a containment failure, the secondary safety function of the barriers is to delay a potential release from the repository.
- The artificial barriers must be made of natural materials that are stable in the long term within the repository environment.
- The repository must be designed and constructed in such a way as to prevent temperatures that can have significant adverse effects on the long-term properties of the barriers.
- The repository must be designed and constructed in such a way as to prevent radiation-induced processes that can have significant adverse effects on the long-term behavior of the artificial barriers or the rock.
- The barriers must be passive, that is, they must function without human intervention and without any artificial input of matter or energy.

Combined with many other considerations, such as the geological context in Sweden and the technical requirements for constructing the repository, these principles led to the development of the KBS-3 system for managing spent fuel.

SKB in Sweden and POSIVA in Finland use the same repository concept, KBS-3, developed by SKB. The KBS-3 repository concept is illustrated in the figure below (Fig. 8).

Fig. 8 KBS-3 concept and closure using clay-based materials. Courtesy of SKB.

The geological repository concept for spent fuel

The principle behind disposal in Forsmark is based on placing spent fuel in copper canisters. The packages will be placed at a depth of around 500 m in the granite host rock. A bentonite (clay) engineered barrier is also planned.

The purpose of the granite rock is to isolate the waste. It provides a stable chemical environment and protection against any events that may occur at ground level. However, the granite substrate also contains groundwater that flows through fractures in the rock. If radioactive substances were to escape from a canister and enter the bentonite, they could be picked up by the surfaces and minerals in these fractures as well as by the micropores of the rock. This is the KBS-3 geological repository concept. The construction, operation and closure of the facility will take place over a period of 70 years.

The copper packages will be disposed of in a vertical disposal cell, in which the clay engineered barrier will be installed. Clay barriers are also implemented in the repository access and operation structures. The disposal cells are closed with a “plug,” disposal drifts are closed with “seals” and cavities are backfilled, etc. The backfill consisting of compacted bentonite clay blocks and granules will be installed in the disposal drifts (Fig. 8).

The repository is designed for 12,000 t of spent fuel contained in approximately 6000 copper canisters. Operation is expected to last 60 years. The repository footprint is planned to cover a 3–4 km² surface area and the disposal cells will be situated at a depth of approximately 500 m (Fig. 9).

Current interim storage of spent nuclear fuels

All spent fuel in Sweden is temporarily stored in the centralized temporary storage facility (CLAB) in Oskarshamn. CLAB is an underground pool-based storage facility that will be integrated into the future spent fuel encapsulation facility in preparation for final disposal (CLINK, future facility at the project stage). This encapsulation plant will condition the spent fuel in copper canisters. Approximately 6000 packages of spent fuel will constitute the total reference inventory of the geological repository (SKB, 2011).

Indicative planning

SKB submitted an application for a license to construct the geological spent fuel repository in 2011. In early 2018, the Radiation Safety Authority (SSM) and the Land and Environmental Court both submitted their opinions to the government. SSM recommended that the government grant permission to move forward. However, the Court requested additional information on the properties of the copper canister and its safety in the long term. In April 2019, SKB submitted additional documentation to the Ministry of the Environment concerning the construction license application for the repository.

Fig. 9 View of repository site at the end of facility life. Courtesy of SKB.

At present, the Ministry of the Environment is continuing to prepare the government's decision and therefore the process of granting a license for the final disposal system for spent fuel in Forsmark. The repository is expected to be commissioned in 2035, following a pilot phase starting in 2030 (SKB, 2019).

Once fully developed—in the 2080s—the repository site will comprise 66 km of tunnels and disposal cells to hold more than 6000 copper canisters containing spent nuclear fuel. At the end of facility life, the repository will have required the extraction of around 2.3 million cubic meters of rock.

On-going R&D programs

Following a long process that began in the 1980s, SKB has carried out geological research involving, among other things, borehole campaigns to characterize the rock. The process of searching for and selecting a site began in 1992. Field investigations began in 2002 and lasted 5 years. The Forsmark site was selected in 2009 as the location for the geological spent fuel repository in a 1.9 billion-year-old granite formation.

In parallel to the site selection, SKB developed a dedicated underground research laboratory, the Äspö Hard Rock Laboratory, north of Oskarshamn, around 460 m below the ground. This work aims to investigate the behavior of the various barriers in the future repository: canister, engineered barrier, and rock; and to test different pieces of equipment for handling the packages. It should be noted that the Äspö HRL is not located near the Forsmark site. The main objective was to provide an opportunity for research, development and demonstration in a realistic and undisturbed rocky environment up to the depth planned for the future final repository.

The Äspö laboratory was constructed between 1990 and 1995. It has been in operation since construction was completed (Fig. 10).

SKB's RD&D programme includes full-time activities at the Äspö laboratory planned until the end of 2023 (SKB, 2019):

- Around 15 experiments are underway,
- Several new large-scale tests are planned.

The purpose of the Äspö HRL continues to be to develop the methodology used to characterize the geological environment that will be used for the repository in Forsmark, the modeling of flows, the behavior of the various barriers, and the validation of digital models.

Fig. 10 Diagram of the Aspo HRL laboratory. Courtesy of SKB.

Finland

The Finnish nuclear waste management programme was launched in 1983, shortly after the four reactors entered commercial operation. The Nuclear Energy Act of 1987 selected the option of disposal and set up the Nuclear Waste Management Fund under the supervision of the Ministry of Trade and Industry. There are no nuclear fuel cycle facilities in Finland. Given that in Finnish legislation spent fuel is classed as radioactive waste, the Loviisa and Olkiluoto nuclear power plants are the main producers of radioactive waste.

Posiva Oy was founded in 1995 as a joint venture between TVO and Fortum, the owners of the Loviisa and Olkiluoto power plants. Responsibility for nuclear waste lies with the electricity companies until it is finally eliminated. Most of the radioactive waste and spent nuclear fuel was produced in the nuclear power plants currently in operation in Olkiluoto (OL1 and OL2) and Loviisa (LO1 and LO2). Spent fuel is currently stored in pools in storage facilities located on the power plant sites. Small quantities of irradiated fuel were produced when the research reactor FİR 1 was in operation in Otaniemi.

The spent fuel to be produced during the service life of units OL1 and OL2 at the Olkiluoto power plant, units LO1 and LO2 at the Loviisa power plant and, finally, of unit OL3 (EPR) currently under construction is estimated at 5500 t of uranium (tU), constituting the reference inventory of the Finnish geological repository.

The Finnish repository concept is the same as that adopted by Sweden, namely KBS-3. It consists of drifts excavated in granite at the Olkiluoto site. In these drifts, vertical (KBS-3V, the reference) or horizontal (KBS-3H) cells are constructed and bentonite blocks are installed, leaving space in the center for the disposal package to be inserted. The disposal package is a sealed copper canister with the spent fuel elements inside (Fig. 11).

Finland began the process of searching for a geological repository site for high-level waste in the late 70s, which included the following major steps:

- the study of potential sites with over 100 pre-selected areas in a granite environment;
- following a complex selection process, five then four areas were characterized in a preliminary manner and then in more detail;
- one site, the Olkiluoto site, was put forward for the construction of a geological repository in 1999, based on the conceptual architecture below (Fig. 12).

Research laboratory

In 2004, Posiva laid the foundation stone by building the research center ONKALO on the future repository site. The purpose of ONKALO was to organize underground research work in a site suitable for the disposal of irradiated nuclear fuel and to provide data on the Olkiluoto rocky substrate. From the start, ONKALO was intended to become part of the future repository. In the future, some parts of ONKALO will continue to have the same requirements as regards research as the former research facility. This site is situated in a granite gneiss-migmatite geological formation, which is approximately 1.8 billion years old.

The ONKALO access tunnel reaches a depth of 455 m. ONKALO has one access tunnel and three shafts: one shaft for personnel and two shafts for ventilation. The slope of the tunnel is 1:10. It is 5.5 m wide and 6.3 m high (Fig. 13).

The research conducted at ONKALO provides additional data on the conditions of the rock substrate and groundwater at the repository site, as well as on the impact of construction on these conditions. This research helps to ensure that the Olkiluoto rock mass is suitable for the repository and to identify areas in which the construction of disposal drifts can be optimized. Several categories of studies and experiments are conducted at ONKALO (Posiva, 2003):

Fig. 11 Posiva repository strategy based on KBS-3 concept. Courtesy of SKB.

Fig. 12 Posiva deep geological repository system based on the KBS-3 concept. Courtesy of Posiva.

- Geological mapping is used to collect data in order to adjust geological models as well as by experts who design reinforcement and grouting measures. Based on this mapping, forecasts are also drawn up concerning the characteristics of the rock at greater depths.
- Probe holes are bored at ONKALO to gather information on the rock to be excavated;
- Characterization niches are also constructed at ONKALO. The first characterization niche was built 1475 m downstream of the tunnel. In total, there are five characterization niches at ONKALO.
- The volume and characteristics of groundwater are studied. Groundwater studies form part of monitoring the consequences of construction.
- Rock mechanics studies serve to determine the conditions prevailing in the rock, such as the direction and intensity of the stress field as well as the strength of the rock. In order to determine the mechanical characteristics of the rock, various types of measurements are carried out before excavation begins in the area in question. The methods can be used both in drillholes and on the excavated surface.

These studies were used to draw up the construction license application for the geological spent fuel repository. Studies are currently being conducted to optimize the design and will be used to support the operating license application file.

Fig. 13 Diagram of the ONKALO laboratory in Olkiluoto. Courtesy of Posiva.

The repository safety concept

Posiva's safety concept is based on the KBS-3 concept, taking into account the properties of the fuel as well as the characteristics of the Olkiluoto site (Posiva, 2012).

Because of the long-term risks it poses, spent fuel must be isolated from the surface environment for an extended period of time. Safe disposal is therefore achieved by isolating and containing the fuel in the very long term. The characteristics that favor long-term isolation and containment include (Fig. 14):

- the copper container encapsulating the spent fuel,
- the bentonite engineered barrier installed inside the disposal cells. It is composed of bentonite blocks put in place before the package is inserted.

Fig. 14 Diagram of the different scales repository-cell-package. Courtesy of Posiva.

The disposal drifts are backfilled with bentonite blocks and the ends of the tunnels are sealed with a specific seal or plug. The function of all of these barriers is to protect the packages and to isolate them hydraulically.

Repository architecture

The disposal drifts are located at a depth of around 400–450 m inside the Olkiluoto granite massif. They will be excavated in the rock and the disposal packages will then be placed in the drilled holes.

The underground site is divided into three parts:

- the disposal drifts where packages containing used fuel will be placed;
- the central tunnels connecting the disposal drifts, the access tunnel and shafts;
- the underground technical auxiliary facilities.

In accordance with the reference inventory adopted, representing approximately 2800 packages to be disposed of, the volume of rock to be extracted for the facility, excluding the waste package disposal cells, is approximately 1.3 million m³. 137 disposal tunnels are planned. The total length of the tunnels has been estimated at 42 km and they are located in a 2–3 km² area.

An access tunnel and four vertical shafts lead from the surface to the repository. The vertical shafts include one shaft for personnel, one shaft for lowering packages and two ventilation shafts. The access tunnel, the personnel shaft and two ventilation shafts were constructed when the ONKALO research laboratory was built. Fig. 15 shows a summary image of the whole repository.

The construction license application for the repository was submitted in 2012. The construction license was granted in November 2015. This came with a set of requirements that Posiva must meet before the repository can begin operation. The first repository excavation works began in 2017.

A second application to the decision-making authorities is required: the operating license application. It will be submitted in 2020. The geological repository is expected to begin operating around 2024. According to current plans, the disposal site will close around 2120.

Summary of the French repository project in clay-rich rock

In France, HLW is mainly produced through the reprocessing of spent fuel from the 19 nuclear power plants (58 existing reactors and the Flamanville EPR under construction). France has chosen to reprocess spent fuel. Ultimate high level waste (i.e., fission products solutions) is conditioned thanks to a specific vitrification process (see dedicated chapter) into stainless steel containers. ILW-LL is more varied. It includes structural components that surround fuel assemblies and residue from the operation and maintenance of nuclear facilities. It is conditioned in metal or concrete containers (Figs. 16–22).

In 1991, the French parliament began to address the problem of managing radioactive waste by passing the “Bataille Waste Management Act” on 30 December 1991. This Act defined the main priorities for research into the management of the most highly radioactive waste. Three research areas were identified: partitioning and transmutation, long-term storage (the CEA was given responsibility for both of these areas) and deep geological disposal, entrusted to Andra, which has conducted research thanks to its underground research laboratory. Andra and the CEA submitted the results of 15 years of research in these areas to the French

Fig. 16 Basic illustration of the CIGEO deep geological repository project. Courtesy of ANDRA.

government in 2005. Based on the outcomes of these extended researches, the French Nuclear Safety Authority (ASN) notably concluded that deep geological disposal seems to be the only definitive management solution possible.

In 2006, on the basis of the scientific results, their review by the ASN and a public debate conducted in 2005, the French parliament ratified the choice of deep geological disposal and tasked Andra with designing a disposal facility in the Meuse and Haute-Marne *départements*. Research is ongoing into partitioning and transmutation as well as storage as complementary waste management options to disposal.

The Industrial Centre for Geological Disposal (Cigeo) project is designed to handle all the HLW and ILW-LL that has been produced and that will be produced by existing nuclear facilities before they are dismantled (nuclear power plants, research centers, etc.). Waste that will be produced by nuclear facilities currently being built (Flamanville EPR, ITER and the Jules Horowitz experimental reactor) has also been taken into account. This represents around 10,000 m³ of HLW and 75,000 m³ of ILW-LL, i.e., around 85,000 m³ of radioactive waste in total. This waste is currently stored temporarily in surface facilities at the sites where it was produced (mainly La Hague, Marcoule and Cadarache), pending its disposal in Cigeo (Fig. 16).

Research into geological disposal, entrusted to Andra by the 1991 Act, draws on various disciplines and covers different aspects, beginning with knowledge of the waste and the rock, as well as the design of the repository, monitoring and the transmission of memory. The gradual process of siting the geological repository will need to be supported by in-depth knowledge (geometry, structure, stability, homogeneity, continuity, etc.) of the geological formations. This characterization of the geological environment is based on regional studies, borehole campaigns, geophysical measurements and observations made in the Underground Research Laboratory.

Underground Research Laboratory

In 1994, investigations were carried out at four candidate sites (in Gard, Vienne, Meuse and Haute-Marne) for the purpose of setting up an underground research laboratory for studying the feasibility of deep geological disposal. The preliminary studies showed that the geology of the Meuse and Haute-Marne sites, now merged into a single site, was particularly suitable:

- The Callovo-Oxfordian formation has a very low permeability. Circulation of water is very limited; a molecule of water travels only a few centimeters in 100,000 years.
- Because of this very low permeability, the radioactive elements move preferentially by diffusion through the rock and this diffusion is very slow.
- The rock has a very high capacity of retention for most radioactive elements.
- The rock contains a significant amount of clay minerals including smectite which fixes elements (and therefore traps the radioactive elements).
- Most of the radioactive elements are not very soluble in the water in the rock (due to the chemical composition of that water).

In 2000, the construction of the Underground Research Laboratory began on this site. Situated at a depth of 490 m and consisting of a network of almost two kilometers of drifts as to the end of 2020, this research facility has been used for scientific and technological research carried out directly within the Callovo-Oxfordian argillite stratum and, in 2005, led to the conclusion that deep geological disposal was feasible (Andra, 2006). The Laboratory is still used for research and experiments for designing Cigeo. Since 2004,

experiments have been conducted to collect geomechanical, geochemical and thermal data. These different measurements required instrumenting the rock that is, carrying out more than 1000 drilling campaigns directly from the experimental drifts, and installing more than 12,000 measurement sensors in the drifts, shafts and at the surface (Andra, 2019) (Fig. 17).

Until 2006, these experiments focused on:

- characterizing the water contained in the rock;
- the mechanical behavior of the rock after excavation;
- the thermal behavior of the rock following heating (which would be induced by HLW packages within the argillite);
- the diffusion and retention properties of the radioactive elements (Fig. 18)

Based on this work in particular, in 2005, a 250-km area around the underground laboratory, called the “transposition zone,” was defined as having identical geology to that of the Laboratory: the argillite formation is stable and its properties will ensure the containment of the radioactivity in the very long term.

Following the Act of 2006 entrusting Andra with the task of designing and implementing a repository, the Meuse/Haute-Marne Centre, which houses the Underground Research Laboratory, entered the industrialization phase of the Cigeo project. New technical and scientific experiments have been set up, focusing on:

- studying changes in the behavior of the rock after excavation;
- testing new excavation techniques (road header since 2009 and partial face excavation machine in 2013);
- excavation tests for HLW disposal cells;
- the behavior of materials within the rock (glass, steel, concrete, etc.);
- the interactions between the materials and the rock.

The scientific experiments that began prior to 2006 are continuing and becoming more complex (thermal tests with three spaced out heating resistors to simulate HLW disposal cells, diffusion tests using radioactive tracers in the argillite, etc.).

In 2009, Andra proposed to the French government a 30 km² underground area inside the transposition zone: the zone of interest for detailed survey (ZIRA). This zone was defined on the basis of both scientific criteria related to the safety and geology of the site and criteria identified by elected representatives and the local population during a consultation. The ZIRA was approved by the government after assessment were issued by the ASN and the National Assessment Board, and after consulting elected officials and the Local Information and Oversight Committee (CLIS) for the Underground Research Laboratory. If Cigeo is licensed, the underground facility will be built in this zone.

The Cigeo concept

Cigeo is designed to remain safe during construction and operation, which will last for around a century, and after its closure (Andra, 2016a,b). The safety of Cigeo relies to a large extent on the geological formation within which the underground facilities will be built. This formation, which has been stable for more than 168 million years, has containment properties that can slow down the transfer of radionuclides contained in the radioactive waste to the surface. Its safety also relies on design choices such as:

- the overall architecture of the repository: the separation of nuclear areas from work areas, for example;
- the facilities and structures: the methods used for excavating and lining the drifts and disposal cells, for example;
- the materials used: non-flammable materials and substances, for example;
- the requirements concerning package characteristics and inspections;
- the instruments and sensors used to monitor changes in the repository as well as to detect any malfunctions;
- the organization system that will be put in place for repository operation: the use of automated and remote-controlled equipment and machinery, for example.

As shown in Fig. 19, the Cigeo project will include two surface facilities: the dispatch zone where waste packages will be received, inspected and conditioned, and the shaft zone used for support for the underground activities and construction works. A double waste package transfer ramp (12% slope) and five shafts for the movement of personnel and transfer of equipment connect the surface and underground facilities. Finally, the underground disposal area will consist of two areas:

- one for the disposal of ILW, with around 20 disposal drifts, 500 m in length (Fig. 20),
- the other for HLW packages, with around 900 disposal cells, 150 m in length (Fig. 21).

A small disposal area set up for an industrial pilot phase will contain 20 disposal cells for slightly exothermic HLW, each 80 m in length.

A reversible repository

In France, ethics with respect to future generations means that action is needed. In particular, given the century-long service life planned for the geological repository, France considers that it is the responsibility of our generation to design a safe facility that we will pass on to future generations, which they are able to modify or improve according to their own objectives and constraints,

Fig. 17 3D view of Andra's Underground Research Laboratory and its 1.8 km of drifts. Courtesy of ANDRA.

Fig. 18 Picture of an underground drift at the Underground Research Laboratory. Credits ANDRA—A. Daste.

or indeed replace with other management facilities, if other options become available, particularly as a result of technical progress. In practice, reversibility is based on governance systems and technical project management tools:

- Governance systems: Continuous improvement of knowledge regarding radioactive waste management, transparency and transmission of information and knowledge, monitoring by the ASN, the involvement of society, and assessment and supervision by Parliament.
- Project management systems: Incremental development and gradual construction of the Cigeo facilities, flexibility offered by their operation, adaptability of the facilities and recoverability of the packages.

Combined with this principle of reversibility, the Cigeo repository incorporates into its architecture the provisions and tools to ensure that waste packages can be recovered, a technological concept complementary to reversibility (Andra, 2016c).

The initial construction of Cigeo will begin when the construction license decree is granted, for which Andra intends to submit the construction license application file to the ASN in 2021. If the license is granted, construction will include:

- the construction of the structures necessary for the disposal facility to be commissioned, so that the first radioactive waste packages can be disposed of, in particular the nuclear building where the waste packages will be received, inspected, prepared and from which the packages will be lowered;
- the excavation and construction of the ramp (sloping tunnel to transport the waste packages to the underground facility);
- the excavation and construction of shafts (vertical shafts connecting the underground facility to the surface and used for the movement of personnel and transfer of equipment as well as for ventilation).
- the excavation and construction of the first underground structures.

In 2030, Cigeo is set to enter an industrial pilot phase (lasting around 5 years), the main objectives of which are to ensure that Cigeo is properly managed and to verify that it functions correctly; to test the results and concepts developed through R&D work, experiments conducted at the surface and in the Underground Research Laboratory and technological tests on a full scale; to acquire, under operational conditions and on a full scale, all the feedback required to make adjustments for the subsequent phases of construction; and, finally, to identify any necessary additions and works that remain to be carried out and thereby inform subsequent decisions.

At the end of this pilot phase, the repository will operate for more than 100 years and will be built progressively as radioactive waste packages arrive. The total surface footprint of the underground repository will cover 15 km².

The first structures to be built will be the facilities needed to conduct the excavation work and start operations at the repository. Once operation of the repository has begun, the underground facility will be constructed as needs arise and in successive phases. The areas under construction will be physically isolated from operating areas. In the same way, the ventilation shafts for the package transfer drifts will be separated from the ventilation shafts for the working drifts (Fig. 22).

In 2020, Andra submitted an application for the declaration of public utility for the Cigeo project to the government in order to reaffirm the public utility of the project. This application is required for all other regulatory procedures, and specifically for operations prior to the construction of the repository. It also makes it possible to finalize the acquisition of plots of land at the surface. This application is accompanied by an overall environmental analysis for the project.

Summary of US repository project in volcanic tuff rock

Prior to 1987, and as required by the 1982 Nuclear Waste Policy Act (NWPA), the U.S. Department of Energy (DOE) selected 10 locations in six states to consider as potential disposal sites for 70,000 t of heavy metals (tHMs) of radioactive waste, including 63,000 tHMs of spent fuel of civil nuclear origin, 2300 tHMs of military origin (managed by DOE) and finally 4700 tHMs of vitrified HLW. This inventory corresponds to approximately 11,500 disposal packages. After detailed studies of the sites, President Ronald Reagan approved three sites for detailed characterization. The three sites were Hanford, Washington; Deaf Smith County, Texas; and Yucca Mountain, Nevada. In 1987, Congress amended the NWPA and ordered the DOE to study only Yucca Mountain. The act provided that if Yucca Mountain were found to be inappropriate, "site characterization studies" would be terminated.

Yucca Mountain is a volcanic ridge with a prominence of nearly 400 m and extending on a north-south axis in Nye County, Nevada, 150 km north-west of Las Vegas on federally controlled lands on the edge of the Nevada Test Site. Yucca Mountain consists of tuff, a rock made from compact volcanic ash formed more than 13 million years ago (Fig. 23).

Yucca Mountain has a desert climate and receives a mean of 125–200 mm of rain per year, depending on elevation a topography. The precipitation in the area presents two seasonal input of meteoric water. In winter, the precipitation is of low

Fig. 23 Aerial north view of Yucca Mountain. U.S. Department of Energy.

intensity and long duration. In summer, rainstorms of high intensity and short duration tend to occur (USGS, 2004). The mountain has a deep groundwater table. The repository would be constructed about 300 m below the earth's surface and 300 m above the groundwater table. Despite the arid climate, unsaturated rocks at Yucca Mountain are not dry: hydrogeological analysis on the tuff media have shown porosities ranging from 10% to 40%, with residual water saturations ranging from 2% to 42%. At the repository level, 90% of modeled water flux occurs in fractures and 10% occurs in the rock matrix (Birkholzer et al., 2006). Within the lower-porosity welded tuffs, performance assessment models show an important capillary diversion of water around the openings in the unsaturated rock and the depth of the groundwater under the repository (Figs. 24 and 25).

Due to these conditions, the unique Yucca Mountain repository concept relies only on the engineered barrier consisting of a primary radioactive waste container made of stainless steel (UoS-DoE, Office of Civilian Radioactive Waste Management, 2008). The radioactive waste packages are emplaced in shields—to divert potential drips and seeps of water—made of a corrosion-resistant titanium metal that would have been placed over the waste packages. The repository design has been defined without backfill allowing ventilation for an extended period providing an effective way to remove radioactive decay heat from the repository and associated heated water vapor into the air fed by the infiltrated surface water (Rechard and Voegelé, 2014).

The measures envisaged to maintain operational safety and to facilitate the potential recovery of packages before closure include the installation of a concrete liner that is 5.5 m in diameter (Fig. 24), or alternatively a steel liner in the event pH changes caused by concrete degradation prove significant.

Rechard R and Voegelé M (2014) Evolution of repository and waste package designs for Yucca Mountain disposal system for spent nuclear fuel and high-level radioactive waste. *Reliability Engineering & System Safety Journal* 122: 53–73. (2014), with permission.

Fig. 25 Geological siting regions. Reproduced with permission of Nagra (2018). *Annual report 2017*. Nagra, Wettingen, Switzerland.

In 1995, a U-shaped tunnel, 7.5 m in diameter and 8 km in length, was dug connecting the surface access portals (North and South). The tunnel is an exploratory shaft facility (ESF) and extends 4 km to the depth of the planned repository (**Fig. 25**).

In 2008, the DOE applied to the Nuclear Regulatory Commission for a permit to build a geological repository at Yucca Mountain.

In February 2009, President Barack Obama's administration, which declared that it was opposed to disposing of spent fuels in Nevada, announced, "Yucca Mountain is not an option for the long term." Funding for the project has been terminated and the Blue Ribbon Commission on America's Nuclear Future has been appointed "to conduct a comprehensive review of policies for managing the back end of the nuclear fuel cycle and recommend a new strategy." The commission concluded there are compelling reasons to move as quickly as possible to develop the disposal, storage, processing and transport of spent fuel and radioactive waste from both defense and civilian sectors. It also proposed important structural developments on the financing, organization and approach needed to conduct these programs. In 2010, the DOE withdrew its construction application filed with the NRC.

Alternative concepts have then been studied, such as the deep borehole disposal concept, which consists of drilling a borehole into crystalline rock to a depth of approximately 5000 m. Canisters containing used nuclear fuel or vitrified radioactive waste from reprocessing would be emplaced within the lower 2000 m of the borehole, and the upper 3000 m of the borehole are sealed. Research and development activities carried out at Sandia National Laboratories from 2009–12 have built the technical baseline for performance of a deep borehole for disposal of nuclear waste ([Sandia National Laboratories, 2012](#)).

In 2013, the DOE announced a new strategy for managing spent nuclear fuel and HLW. This included centralized waste storage, then mixing commercial and defense waste into a single repository—which would be operational by 2048—at a site other than Yucca Mountain. The Blue Ribbon Commission recommended the establishment of an independent agency to manage radioactive waste, the Nuclear Waste Administration. It would be entrusted with the responsibilities and missions currently carried out by the DOE in the area of waste, including defense waste.

In 2015, President Obama indicated that a separate repository for defense-related radioactive waste was needed. The DOE stated that defense waste is smaller in volume, less radioactive, and thermally colder than commercial irradiated nuclear fuel, indicating that a defense facility could be easier to develop. Following this announcement, the DOE declared its intention to build two disposal facilities, one for most of the country's defense-related radioactive waste and the other for commercial irradiated nuclear fuel and residual defense waste.

In 2016, the National Defence Authorization Act for Fiscal Year 2017 denied funds for a repository solely for defense waste.

In 2018, President Trump's budget request for fiscal year 2019 included \$120 million for the resumption of the review of the Yucca Mountain repository construction permit application and associated surface storage of the radioactive waste inventory concerned. As of February 2019, the Congress had not allocated funding for the resumption of the permit application.

As to the end of 2020, the waste management policy in the USA is currently in a dead end. Yucca Mountain project did not resume up to now and no alternative projects emerged.

Overview of other projects: Switzerland, Belgium, Japan and Russia

Switzerland

The reference long-term solution for all radioactive waste in Switzerland is deep geological disposal. Since the 1980s, scientific research on geological disposal has been conducted on two host rocks: clay and granite. Two underground laboratories were built:

- from 1983, in Grimsel, in the granitic massif next to the Oberhasli hydroelectric power plant;
- and since 1996, at Mont Terri, in the layer of clay crossed by the motorway tunnel of the same name.

These are "methodological" laboratories that serve to expand knowledge about some of the scientific and technical aspects related to the geological disposal of high and intermediate-level long-lived waste (HLW/ILW-LL).

For spent fuel, vitrified HLW and ILW-LL, Nagra, the National Cooperative for the Disposal of Radioactive Waste in Switzerland, has demonstrated the feasibility of clay disposal at Opalinus in the Zürcher Weinland. The reports documenting the study were submitted to federal authorities in 2002 (Nagra, 2002).

In 2005, Nagra concluded that repositories in the crystalline subsoil were feasible and that long-term safety was possible, but geological field data did not provide a clear conclusion regarding the availability of sufficiently large areas of appropriate crystalline rock. Thus, it was concluded that the feasibility of the implementation had not been fully demonstrated.

In June 2006, the Swiss Federal Council, relying on its competent bodies, confirmed that the proof of feasibility required by law had been established for the waste concerned. The decision was not intended to designate a particular site, but to attest to the feasibility of a deep geological repository in Switzerland, as required by the Nuclear Energy Act. The demonstration of feasibility served as a basis for the Federal Council to determine the continuation of the procedure for the final disposal of these wastes.

Nagra's process of searching for a clay disposal site in Switzerland consists in choosing a site and disposal concept from several sites preselected on geological and socio-political criteria. The process will converge on a (geographic) site with an associated disposal concept in 2022.

The total volume of the radioactive waste inventory taken as reference for geological disposal is 92,000 m³. This includes 9400 m³ of HLW representing 479 containers or packages to be placed in the underground facility.

Site selection process

The process of selecting a deep geological repository site is governed by the Deep Geological Repository Sectoral Plan (Swiss Federal Office of Energy SFOE, 2008) in accordance with the Nuclear Energy Act and Land Use Planning Act. The objective of the Swiss government's process is to identify deep geological disposal sites as framework of a large-scale procedure. Safety is the top priority, but socio-economic aspects and regional planning also play a role.

The search for safe sites is implemented in such a way as to meet all of the objectives for protection formulated by the authorities and which can be achieved from the point of view of regional planning. The Sectoral Plan provides for a comprehensive coordination of all spatial impacts of deep geological disposal and ensures the early participation of cantons, communities and authorities from neighboring countries, as well as interested organizations and associations.

Phase 2 of the site selection process was completed by the Swiss Federal Council in late 2018 and Switzerland is currently in the third and final stage. Nagra studied in detail the other three areas of Jura-Est, Nördlich-Lägern and Zürich-Nordost, and then compared them with each other. The program of investigation includes seismic campaigns already conducted, as well as quaternary and deep exploratory drilling. The results of deep drilling will supplement the overall geological picture of the underground environment in the locations.

Based on the results of the earth science studies, Nagra will announce the site(s) for which it will prepare general permit applications around 2022. Nagra will then prepare the applications and plans to submit them by 2024.

According to the Sectoral Plan, a repository for HLW will not be available before 2060 (Fig. 26).

Geological disposal concepts

The spent fuel/HLW disposal packages would be leaktight for a long time and constructed of thick black steel (12–14 cm) or a copper shell.

According to the current reference concept (Nagra, 2014), each disposal canister will be flooded in an appropriate buffer material consisting of bentonite blocks for placing the package and a (very compacted) granular bentonite mixture (GBM) for

Fig. 26 Schematic of emplacement design at Yucca Mountain. Birkholzer JT, Webb SW, Halecky N, Peterson PF and Bodvarsson GS (2006) Evaluating the Moisture Conditions in the Fractured Rock at Yucca Mountain: The Impact of Natural Convection Processes in Heated Emplacement Drifts. *Vadose Zone Journal* 5: 1172–1193. (2006), with permission.

filling the voids. The disposal tunnel will be filled with GBM after each disposal canister is emplaced. The bentonite material and the backfilling procedure must meet several long-term safety and technical feasibility requirements (Nagra, 2019) (Fig. 27).

Access tunnels will also be partially filled with sand/bentonite mixtures. A prototype filling machine was designed and built as part of a test at the Mont Terri Methodological Laboratory in Switzerland.

The architecture of the HLW repository is in the design stage. The depth of the repository is highly dependent on the site. The clay formation at Opalinus is generally more than 100 m thick and is surrounded by clay-rich containment units. The repository is connected to the surface via a shaft and/or ramp. The concept has been engineered in depth, from 400 to 900 m. The disposal tunnels for spent fuel or HLW are up to 800 m long and have an internal diameter of 2.8 m (Fig. 28).

The deep geological repository will consist of an underground laboratory, pilot facility and main repository. Prior to excavation of the future deep geological repository, an underground laboratory is first built at the site. The laboratory performs experiments directly in the host rock to verify the characteristics of the chosen location (in operation between 2032 and 2048, according to the Nagra estimate). Only when the acquired data meets the stringent security requirements can excavation begin on the other parts of the facility that are planned for 2049 and 2059 (first the pilot facility, then the main repository). The pilot facility is used to emplace waste characteristic of the repository to observe its behavior over a long period of time. Both the underground laboratory and pilot facility enable verification of the essential assumptions and parameters that form the basis of the barrier and disposal concept. Long-term disposal in the main radioactive waste repository will begin as soon as the pilot facility is filled.

A concept for disposal of LILW and HLW at the same site is also under consideration (Fig. 29).

Belgium

In practice, the national program has adopted an approach based on waste management streams, where the streams are defined according to the ultimate destination (planned or not) of the waste. More specifically, the following main types of waste (and their prospective inventory in 100 years) are taken into account for geological disposal, although the Belgian government has not yet taken the decision:

- conditioned LILW-LL, also known as category B waste (corresponds to intermediate activity waste according to the IAEA Classification of Radioactive Waste, 2009), 11,100 m³ over 100 years;
- conditioned HLW, also known as category C waste, which include unprocessed spent fuel from nuclear power plants and certain research reactors declared as waste and vitrified waste from reprocessing spent fuel from nuclear power plants (corresponds to HLW in the IAEA classification), 4500 m³ over 100 years.

The CEN SCK (Center for the Study of Nuclear Energy) launched the research, development and demonstration for geological disposal of HLW and ILW in 1974. Beginning in the early 1980s work continued under the auspices of Ondraf/Niras (the Belgian national agency for radioactive waste and enriched fissile material), which retained CEN/SCK as its main research partner. Having begun work in 1980, CEN/SCK completed construction on the HADES underground laboratory in 1987. Located at Mol at a depth of 225 m, in the heart of the Boom Clay layer, it is the first underground laboratory in Europe, built in a deep clay formation to study the possibility of geological disposal in clay. The layer has an average thickness of about 100 m.

In 1995, researchers launched the PRACLAY project. The purpose of the project is to demonstrate the possibility of using industrial techniques to construct a repository in poorly indurated clay. The project tested the construction methods of an actual disposal facility. During the first phase of the project, a second access shaft was added to HADES. The shaft was then connected to the existing part of the laboratory. In 2007, the PRACLAY gallery was dug perpendicular to the connecting drift to host a large-scale heating experiment: the second phase of the PRACLAY project. The experiment will study the effect of heat released on the deep clay layer. It is also intended to examine the extent to which excavations influence the behavior of the clay layer (Fig. 30).

Fig. 30 The HADES underground laboratory was built in two phases. Courtesy of ONDRAF-NIRAS.

HADES was built in a layer of poorly indurated clay at a depth of about 225 m. Two phases of construction have been completed:

- a construction phase by manual excavation after freezing between 1980 and 1987. The first phase included excavation of the first access shaft, two drifts and an experimental shaft.
- a construction phase using tunneling machines between 1997 and 2007. The second phase saw excavation of the second access shaft, the connecting drifts and PRACLAY.

Several canister options are under consideration for vitrified waste and spent fuel:

- the Vitrified waste supercontainer (37,147 tons, 4077 m height and 2144 m diameter)
- the spent UOX supercontainer (variable mass from 46,851 to 69,711 tons, variable height from 4193 to 6122 m and 2165 diameter)
- the spent MOX supercontainer (35,202 tons, 5498 m height and 1724 m diameter) (**Fig. 31**)

Ondraf/Niras took the initiative, in 2011, to bring together in one document, *Plan déchets* (Waste Plan), all the elements necessary to make a “decision in principle” concerning Belgian policy on the long-term management of HLW and ILW-LL (including used fuel if declared as waste). The document, accompanied by a Strategic Environmental Assessment (SEA), was submitted to a SEA Committee, the Belgian Federal Council on Sustainable Development and regional governments, as well as the public. Ondraf/Niras also submitted the documents for an opinion from the Belgian Federal Agency for Nuclear Control (FANC). In 2015, Ondraf/Niras resubmitted the Waste Plan in order to comply with the European directive on radioactive waste transposed into Belgian law.

Studies for the long-term management of HLW/ILW have so far focused on geological disposal in poorly indurated clay (found at Boom or Ypres). The disposal options for this waste have evolved since 2011:

- 2011: Proposal by Ondraf/Niras, in the Waste Plan, to retain geological disposal as a long-term reference solution using poorly indurated clays at a depth of 225 m at the Mol site;
- mid-2018: Following the request of the supervisory ministries and FANC, a new proposal was made without specifying the host rock and the number of sites;
- Late 2018: A new architecture was proposed for geological disposal on a single site located in Belgium with poorly indurated clay at a reference depth of 400 m. Authorization is scheduled for 2050.

There has not yet been a “decision in principle” at the federal level regarding the long-term management of HLW and ILW-LL. Without a national policy for the long-term management of B and C waste in Belgium, there is no preferred rock or site. Seeking to optimize the process, FANC requested that all potential host rocks be considered. There is no dedicated and comprehensive regulation on the site search process or the status of spent fuels. Ondraf/Niras was legally responsible for proposing management policies as well as for concepts for radioactive waste disposal.

Fig. 31 Concepts of Vitriified waste supercontainers (A), Spent UOX supercontainers (B) and Spent MOX supercontainers (C). (A-C) Courtesy of ONDRAF-NIRAS.

Repository concept for B and C waste

Several options are under consideration for canisters for vitriified waste and spent fuel. Their diameter is approximately 2.1 m and between 4 and 6.1 m in length. The weights vary between approximately 37 and 70 tons. The containers provide radiation protection.

The repository design for B and C waste builds on the combined experience and knowledge gained on Boom clay in HADES. The proposed site for the construction of a geological disposal in 2011 was therefore Mol ([ONDRAF/NIRAS, 2013](#)).

FANC, in its “FANC Opinion on the National Spent Fuel and Radioactive Waste Management Programme” (April 2015), expressed its preference for geological disposal, a term that includes the options of underground drifts and deep drilling. In contrast, FANC considers that it is not possible to make a decision on the host “poorly indurated clay” formation proposed by Ondraf/Niras, due to the lack of systematic comparison of potential host formations, as well as isolation, which is not sufficiently addressed, particularly concerning the presence of usable groundwater reserves (aquifers) adjacent to the proposed host formation.

In 2018, after the opinion was issued, Ondraf/Niras proposed a new concept taking into account the following characteristics:

- site depth between 200 and 600 m;
- measures to support flexible decision making, package recoverability and repository monitoring;
- special attention paid to operational safety.

The reference schedule has thus been changed. It is expected to be operational in 2050. The surface area of the disposal is approximately 4 km². The number of disposal drifts, 400 m long, is 42 for C waste and 37 for B waste. The B waste and C waste sections are separated by the shaft area ([ONDRAF/NIRAS, 2020](#)) ([Fig. 32](#)).

In 2020, Ondraf/Niras submitted to FANC, for its opinion, the revision of the long-term management plan for conditioned HLW and ILW-LL in Belgium, the accompanying environmental impact report and the associated non-technical summary.

Several months later, FANC gave its opinion stating that geological disposal, whether in drifts or deep drilling, is the safest long-term management option for HLW and ILW-LL taking into account current knowledge. This is based on the following technical considerations:

- a repository ultimately based on exclusively passive measures appropriate to such waste;

Fig. 32 Conceptual repository architecture during operation. Courtesy of ONDRAF-NIRAS.

- this type of waste requires a level of containment and isolation that can only be provided by geological formation at an adequate depth;
- this option limits burdens on future generations and helps to avoid uncertainty about its context.

FANC notes, however, that in subsequent stages of the decision-making process, the safety of geological disposal in Belgium will still need to be demonstrated on the basis of safety files within the framework of a decision-making process to be defined.

Japan

Within the framework Japan's nuclear power programme, the safe management of the resulting radioactive waste, particularly vitrified HLW from fuel reprocessing, has been a major concern and a focus of R&D since the late 1970s. The *Second Progress Report on R&D for the geological disposal of HLW* (Report H12) was published after two decades of R&D activities and shows that HLW disposal in Japan is feasible and can be implemented at sites that meet certain requirements for geological stability. The report supported the government's decisions that were the basis of the Act on Final Disposal of Specified Radioactive Waste, which came into force in 2000. The Act on Final Disposal specifies that deep geological disposal of HLW must be carried out at depths greater than 300 m, and that a three-step site selection process must be completed: selection of preliminary investigation areas (PIAs), selection of detailed investigation areas (DIAs) and selection of a geological disposal construction site.

Created in the same year, by the Act on Final Disposal of Specified Radioactive Waste, the Nuclear Waste Management Organisation of Japan (NUMO) is the body responsible for geological disposal of vitrified HLW from reprocessing spent fuel used in nuclear power plants. In 2007, the act was revised, extending the inventory of geological disposal to TRU wastes containing over a certain concentration of long-life radionuclides (transuranic type) generated by the operation and dismantling of reprocessing plants and MOX fuel fabrication plants.

This will consist of 40,000 containers of vitrified HLW and 18,000 m³ of TRU waste.

As part of its search for a site, NUMO issued a call for applications from municipalities in 2002. A few sites expressed interest in the project, including the city of Toyo in Kochi Prefecture. However, it withdrew its application in 2007. Given the failures and a social context which rejects nuclear energy following the Fukushima accident in December 2013, the Japanese government officially adopted a new procedure for selecting a geological disposal site. It provides that the competent authorities first propose a selection of appropriate sites, on the basis of scientific investigations, before seeking a local consensus on one of them. In May 2015, the procedure was amended to make the government more proactive in preparing the local consensus.

The final choice of the site to host the repository is planned for 2025, with operation scheduled to begin in 2035.

Underground laboratories

Parallel to site searches, the Japan Atomic Energy Agency (JAEA) continues its research programs. To date, there are two underground laboratories, the first in Mizunami at a depth of 500 m in crystalline rock, and intended to reach 1000 m,

Fig. 33 Locations of the two JAEA underground laboratories and surface R&D facilities. Courtesy of JAEA.

and the second in Horonobe, at a depth of 500 m in clay (Hama et al., 2016). In surface R&D, JAEA operates two major facilities (ENTRY and QUALITY) at its Tokai site. They study geological and engineered materials in repository conditions (Fig. 33).

Repository concept

In Japan, it was decided that the waste will be placed in a stable rock formation at a depth of more than 300 m. A multi-barrier system consisting of artificial and natural (geological) barriers will isolate and contain radioactive waste over a long period of time (NUMO, 2013).

The future repository site will consist of surface installations where vitrified HLW will be encapsulated in steel overpacks and TRU waste in steel primary steel containers, before being grouped into concrete overpacks (Fig. 34).

Underground facilities will include tunnels for the transport and disposal of waste packages and will be built in a stable rock formation more than 300 m underground. The underground project includes construction of disposal drifts, emplacement of waste packages and backfilling of disposal tunnels. There will be two large separate HLW and TRU disposal areas for parallel disposal operations (Fig. 35).

The repository is scheduled to operate for 60 years, after which it will be continuously monitored for 300 years.

NUMO plans to build a disposal site, with surface facilities extending over 1–2 km², with the surface area of the underground facilities:

- for disposal of HLW packages, 3 by 2 km;
- for disposal of TRU packages, 300 by 500 m (Fig. 36).

Russia

A site search for a geological repository has been conducted for more than 20 years. The Radioactive Waste Management Act and the amendment of certain legislative acts (Federal Law 190-FZ of 11 July 2011) constitute the first legislative act regulating the

Fig. 34 Illustration of methods for packaging HLW and TRU wastes. Courtesy of NUMO.

end of the fuel cycle. This legislative framework distinguishes radioactive waste from spent fuels and proposes a classification into 8 categories according to lifetime (short or long) and level of activity (VLLW, LLW, ILW, HLW). The law also created a national radioactive waste management operator, NORAO, in charge of developing a geological disposal solution for class 1 and class 2 radioactive waste:

- Class 1 waste: exothermic liquid or solid HLW,
- Class 2 waste: non-thermal liquid or solid HLW, sealed sources and ILW-LL

The results of the investigative studies of the Yeniseisky site in Krasnoyarsk, in the immediate vicinity of ZATO Zheleznogorsk, in the gneiss rocks of the Nizhnekansky massif have made it possible to draw a conclusion on the suitability of the geological environment for disposal of radioactive waste in the Archean gneisses within the target depth range of 450–550 m. The methods of studying the geological environment and the results of deep drilling cannot provide all the necessary and reliable information on both the interaction of deep structures with host rocks and groundwater and the processes occurring in the “waste—technical barriers—geological environment” system.

In 2012, the site was recognized as an ideal candidate for the construction of an underground laboratory.

Fig. 35 Conceptual illustration of the future geological repository. Courtesy of NUMO.

In 2016, NORAO received authorization to construct an underground laboratory and published the *Strategy for Creating a Deep Disposal Site for Radioactive Waste* in 2018 (NORAO, 2018). Justification for the possibility of transition from laboratory activities to the industrial operation of the disposal facility will be presented on the basis of the results of the research.

The creation of an underground research laboratory will enable the implementation of a research complex covering the following areas:

- studies of rock mass under natural conditions, determining possible ranges in variation of important parameters to assess containment safety;
- experimental studies of the long-term confining properties of technological barrier materials under conditions including thermal influences and water saturation;
- development of technical solutions for design, construction of technological barriers and disposal of radioactive waste;
- development and testing of equipment, technical resources and methods of operating mine sites;
- verification of mathematical models to assess the behavior of the entire multi-barrier system to justify safety;
- demonstration on a real or reduced scale of the possibility of sealing the disposal chambers (Fig. 37).

Upcoming deadlines set by NORAO include:

- 2019–23: field and laboratory studies of rock mass during the construction of vertical and horizontal structures of the underground laboratory;
- from 2024: pilot research and development of technological operations in the underground laboratory;
- after 2028: review of the results of pilot studies in the underground laboratory.

Conclusion

In most of the countries that have developed military or electronuclear programs, numerous technical solutions for the SNF and HLW management have been imagined and studied for the past 70 years. Management methods such as extended long-term storage, reducing their dangerousness by transmutation, sending them into space, evacuating them to the seabed or in the magma, disposing them of in the geological environment, have all been thoroughly analyzed and evaluated (IRSN, 2019). Of these, deep geological repository is the only management method whose feasibility has been proven and which can handle all SNF and HLW (OECD/NEA, 2020). It is the international benchmark for the sustainable management of this waste. None of the alternative modes of management currently envisaged would allow a sustainable and secure management of all SNF and HLW inventories, around the world, already existing and to be produced. All the alternative solutions would still require research and very significant investments in the hope, not guaranteed, of removing the technological obstacles to their use today.

Following a universal ethical requirement, their sustainable management aims at permanently securing them to prevent or limit any burden on the future generations. The current generations are indeed benefiting from the nuclear activities. It is their responsibility to deploy technical options insuring the safe and sustainable management of SNF and HLW, without passing on the burden from one generation to the next indefinitely.

As illustrated within this article, the development of a geological repository is a long process, divided in different stages and based on a stepwise approach. Achieving progress in many national disposal programs is difficult, owing to institutional, administrative and economical aspects, reticence among decision makers to deal with controversial issues and the opposition of stakeholders. Over the past 30 years, several geological disposal projects have been impeded or even halted due to vehement or even violent opposition. The ineffectiveness or absence of stakeholder involvement has altered acceptability and resulted in important obstructions to programs progresses. The introduction of national and local public debates along with the development of deep geological repositories around the world in the early 2000s has proven the crucial importance to involve the national public and local stakeholders in the projects' development decision-making and through concertation. Because of changes in society's decision-making environment and increased public sensitivity to all matters connected with environmental protection, nuclear power, radioactivity, and especially radioactive waste, any decision regarding whether, when and how to implement waste management solutions nowadays typically require thorough public examination and the involvement of many relevant stakeholders (OECD/NEA, 2004).

Certain countries facing such public refusal for hosting a national deep geological repository and some of the 30 countries with a small inventory of SNF/HLW (<3000 tHM) have together explored the practicalities and implications of sharing some elements of their radioactive waste management strategies—specifically, sharing one or more deep geological repository sited within one of the interested countries, rather than each developing its own facilities. Since 2004, the national benefits of being part of a multinational shared geological disposal program have been studied (IAEA, 2004; ERDO, 2013). They were identified as achieving a clear demonstration of a credible approach to responsible management of national radioactive wastes; a reduced R&D burden; increased, pooled resources to develop a realistic and timely solution; large economic incentives and infrastructure improvements to the host country and access to wider skills and technology. Multinational shared repositories being seen as a real opportunity for certain countries and thus implementing the “wait and see” approach, International organizations are recommending to develop their own national program following a “dual track” approach that includes working cooperatively with other interested countries toward shared solutions (IFNEC, 2016; IAEA, 2016). As of today, considering the important remaining challenges both at the legal and technical levels (environmental impact liability, integration of important chemical/radiological variability of conditioned SNF or HLW, etc.) multinational waste disposal facilities are criticized as not being credible until such time as a country agrees to host one.

Actinide production and inventories

Actinide elements, whilst a valuable resource for scientific study due to their rich chemistry, present a unique challenge with respect to radioactive waste management, due to their long half-lives, high radiogenic heat output, and chemical toxicity (see Table 1). With the exception of U and Th, which exist primordially in appreciable quantities, the actinide series is produced synthetically, as the result of either transmutation and decay processes occurring within commercial and experimental nuclear reactors. The production of Pu isotopes poses an aggrandized risk, insofar as these isotopes are separated in considerable quantities, with relatively small critical masses capable of sustaining a fission reaction, and are therefore subject to proliferation safeguards. Under conventional operating parameters, a civilian reactor operating in the burn-up range 35–45 MWd kgU⁻¹ will produce around 1 at.% Pu, among other transuranic (TRU) elements at around 0.1 at.% (Ewing, 2015). It should be noted that the isotope distribution of Pu at discharge is a generally a function of reactor design, fuel type, initial ²³⁵U enrichment, and burn up (Table 2). The remaining spent nuclear fuel (SNF) matrix is comprised of approximately 96 at.% U, with 3–4 at.% entrained fission products (FP). Notable high yield constituents that require consideration for immobilization include

^aMoD reporting in 2000.

^{129}I ($t_{1/2} = 15.7$ My) and ^{137}Cs ($t_{1/2} = 30.2$ y), and activation products originating from neutron activation of cladding materials e.g., ^{55}Fe ($t_{1/2} = 2.7$ y). Operating a reactor to a higher burn-up affords a greater yield of minor actinide (MA) species, which form a significant contribution to the overall radioactive output of the SNF matrix, often with considerable half-lives. Notable examples of MA species, for which immobilization options have been considered include ^{241}Am ($t_{1/2} = 433$ y), ^{239}Pu ($t_{1/2} = 21,400$ y), ^{237}Np ($t_{1/2} = 1.2$ My) and ^{237}Cm ($t_{1/2} = 1.56$ My). At fuel discharge there remains the option to implement an aqueous reprocessing procedure, whereby the SNF matrix is dissolved and actinides are targeted for solvent extraction, thus decreasing the radiogenic output associated with the fuel matrix, and allowing the separation and recovery of fissile material. Currently, only the PUREX (plutonium-uranium-reduction-extraction) process has been deployed at the industrial scale, examples of which are reprocessing plants integrated into the back-end of commercial fuel cycles in France (La Hague; capacity ~1600 tHM/year) and the United Kingdom (Magnox; capacity ~1500 tHM/year). During the reprocessing stage, the irradiated UO_2 pellets are sheared of cladding, prior to dissolution in a hot solution of 3–6 M HNO_3 . Pu^{4+} and U^{6+} may then be extracted to an organic phase via complexation with 20–40 vol.% tri-butyl-phosphate (TBP) diluted in inert kerosene, and separated from the residual

Belgium	< 50 kg	44
Switzerland	< 2 kg	20

high activity liquor (HAL) containing the remaining MA and FP contaminants. Pu is subsequently separated from U through a reductive backwash, and reclaimed via formation of insoluble $\text{Pu}^{4+}(\text{C}_2\text{O}_4)_3 \cdot 6\text{H}_2\text{O}$ and $\text{Pu}^{3+}_2(\text{C}_2\text{O}_4)_3 \cdot 10\text{H}_2\text{O}$ precipitates with the addition of oxalic acid, prior to calcination and storage as PuO_2 . It should be noted that the PUREX process, and subsequent separation of U & Pu has formed the most significant contribution to existing actinide stockpiles internationally, as this is the only process demonstrated on any industrial scale. Indeed, the development of future nuclear fuel cycles may necessitate the implementation of advanced MA recovery separations, significantly reducing the radiothermal output associated with high level waste (HLW) packages prior to geological disposal. Concepts for integrated MA reprocessing cycles include TALSPEAK (trivalent actinide-lanthanide separations by phosphorous-reagent extraction from aqueous complexes) and ALSEP (actinide-lanthanide separations process). However, as such MA solvent extraction processes only occur on small scale, in particular the separation of ^{237}Np as a precursor for ^{238}Pu production for radioisotope thermoelectric generators (RTG), and are not stockpiled in considerable quantities, it is largely the isotopes of separated Pu that are considered when discussing the stockpiling of actinides. Nevertheless, the development of advanced materials capable of acting as immobilization hosts for MA constituents remains an active area of research. For a comprehensive discussion of advanced reprocessing techniques pertaining to separation and partitioning of actinides, the reader is referred to [Nash and Nilsson \(2015\)](#).

Internationally, over 340 metric tonnes of Pu were declared as holdings to the International Atomic Energy Agency (IAEA) in 2017, reported under INFCIRC/549 obligations of the Treaty on the Non-Proliferation of Nuclear Weapons (NPT) ([Table 3](#)). Some nations have implemented a management strategy whereby Pu is reintegrated into the fuel cycle, through the fabrication of mixed oxide (MOX) fuels for reuse in existing reactor fleets. However, it is disconcerting to note that there exist some significant inventories of unirradiated Pu held at surface facilities. For example, the United Kingdom is in a unique position insofar as it holds an inventory of unirradiated Pu forecast to reach approximately 140 teHM (tonnes heavy metal equivalent) currently held under civil safeguards. There is a growing consensus that the indefinite storage of such material is not a satisfactory approach to long term management, as this is in contravention of security and non-proliferation safeguards. Hence, it is necessary to implement a strategy favoring either reuse or prompt disposal. For example, the bulk of the United Kingdom civil inventory could be utilized to support a campaign of energy production, through fueling a fleet of a three 1100 MWe Pressurized Water Reactors (PWR) for around 60 years. For a comprehensive review of Pu management policy in the context of the United Kingdom inventory, see ([Hyatt, 2020](#)). Nonetheless, the implementation of such a strategy is controlled by commercial appetite for MOX fuel, which has not been presented in the United Kingdom. In some instances, the accumulation and long-term storage of Pu presents an additional challenge of materials degradation. For example, it is estimated that ~ 5 t of United Kingdom Pu has succumbed to contamination through radiolytic degradation of the interim storage containment, hence regardless of the chosen pathway to disposition, it is advisable to develop long-term management strategy that can account for some portion, if not bulk inventories, to be designated as waste for disposal. There is a generic consensus that the end point of all ILW and HLW waste-streams, including actinide inventories, is geological disposal, subsequent to the design of a suitable wasteform.

Purpose and design requirements of nuclear wasteforms

As a precursor to the long-term disposition of nuclear waste inventories, it is necessary to convert, encapsulate or solidify the feed-stock into a product with improved chemical and physical stability than the source material, offering improved characteristics with respect to handling, transport and disposal. To convert material in such a manner is termed *immobilization*, with the product referred to as the *wasteform*. Demonstrated practices of immobilization include vitrification, cementation, bitumenization and ceramification ([Ojovan and Lee, 2005](#)). The conditioning of waste in such a manner is a precursor towards ultimate disposition, the foreseen pathway for which is disposal in an engineered facility. The geological disposal facility (GDF) concept is considered to be the only technically mature option for the permanent disposition of intermediate and high level wastes, whereas surface disposal routes are deemed applicable to wastes with low levels of activity (< 4 GBq/t α). The safety case for geological disposal is underpinned through the multi-barrier concept, a system whereby the encapsulation or immobilization matrix acts as the primary layer of containment,

Fig. 1 Multibarrier concept for the immobilization and geological disposal of ILW, HLW and actinide-rich material.

which is subsequently over-packed and backfilled to retard water groundwater ingress, obviate corrosion and extend the lifetime of the package integrity, ultimately mitigating the release of radionuclide material into the near field environment, for such a time period that the overall activity of the waste is comparable to that of the natural uranium ore from which it was derived (Fig. 1). A sound disposal strategy stipulates that the choice of wasteform is tailored to suit the physical and chemical properties of the feedstock, as the immobilization matrix itself is considered to act as the primary containment, with the fundamental objective the reduce the potential for radionuclide dispersion into the near field environment. A set of generic wasteform design criteria is outlined below. For HLW wastes, typically concentrated raffinate derived from the reprocessing of SNF matrices, the thermal treatment of choice is calcination prior to vitrification in a borosilicate glass matrix (Table 4). Glass is a suitable candidate on the basis that a wide array of constituent elements comprising HLW are soluble in the glass matrix, either through substitution within the glass network (Si^{2+} , B^{3+} , P^{5+}) or as network modifiers (Cs^+ , Na^+ , Li^+ , Mg^{2+}). The vitrification process is continuous, utilizes relatively low melting temperatures ($\sim 1050^\circ\text{C}$) and is relatively insensitive to the nature of the wastestream, allowing the glass composition to be easily modified to accommodate small variations in feedstock. Upon cooling, the wasteform is a homogeneous product with a relatively high chemical durability ($\text{NL}_{\text{Si}} = 0.011 \pm 0.004 \text{ g m}^{-2} \text{ day}^{-1}$ based on 1:3 Magnox-ThORP blend with 25% simulant waste loading at $T = 23^\circ\text{C}$ and $\text{pH} = 8$; see (Cassingham et al., 2015). Despite the efficacy of borosilicate glass to accommodate HLW, the solubility of actinide-rich feedstocks in glass is relatively low. Using Ce as a surrogate for Pu, (Lopez et al., 2003) determined that Ce solubility in borosilicate glass was a function of temperature and $\text{Ce}^{3+}/\text{Ce}_{\text{total}}$, increasing from 0.25 wt.% at 1100°C to 15 wt.% at 1400°C , corresponding to an increase in the $\text{Ce}^{3+}/\text{Ce}_{\text{total}}$ ratio from 0.5 to 0.9. This reduction protocol was utilized by (Cachia et al., 2006) to increase the solubility of PuO_2 from $\sim 2 \text{ wt.}\%$ to $\sim 4 \text{ wt.}\%$. However, through the success of the SYNROC wasteform, alternative crystalline wasteform materials are favored for actinide immobilization, as it is considered these will offer superior wasteloading and durability.

Table 4 Compositions of selected nuclear waste glasses (wt.%).

Waste glass	SiO_2	B_2O_3	Al_2O_3	CaO	MgO	Na_2O	Other	Waste loading
R7T7 (France)	47.2	14.9	4.4	4.1	–	10.6	18.8	<28

Ceramic wasteforms for actinide immobilization

Multiphase SYNROC

Despite the suitability of borosilicate glasses for the vitrification of chemically heterogeneous HLW waste streams, single and multi-phase ceramic phase assemblages are generally considered to offer superior durability in the geological environment, alongside, in some instances, greater wasteloading of actinides. Ceramics offer a high performance solution for separated elements, as an alternative to vitrified wasteforms, and pertain to the substitution of the waste cations into a specific lattice sites within a crystalline structure, whilst retaining long-range order. Hence, tailoring ceramic materials for the effective immobilization of radionuclides requires additional considerations with respect to the relative size and accessible valence state compatibility between waste cations, and the targeted substitution site within the host structure. Such a design philosophy essentially allows the waste constituents to adopt the physical and chemical properties of the host material, hence ceramic immobilization is typically informed through the study of natural mineral analogs in the wider environment. Mineral specimens that remain present in the environment, having exhibited resistance to natural weathering processes over 10^6 years, are therefore excellent candidates from which to design synthetic ceramic materials for actinide immobilization. Ringwood et al. (1979) developed and proposed SYNROC (*synthetic-rock*) as alternative candidate ceramic wasteform for HLW and actinides. The SYNROC wasteform is a collection of thermodynamically stable titanate ceramic phases, chosen due to their extensive geochemical stability in the natural environment, and ability to accommodate the vast majority of elements comprising HLW waste streams. The dominant phases present in most variations of SYNROC are hollandite, zirconolite, perovskite and rutile. Hollandite, ideally $\text{Ba}_x(\text{Al,Ti})_{2x}\text{Ti}_{8-2x}\text{O}_{16}$, is predominantly included as a host for processing contaminants and fission products. The hollandite structure is comprised of a framework of corner and edge sharing TiO_6 and AlO_6 polyhedra parallel to the c-axis of the tetragonal unit cell, allowing large mono or divalent A-site cations (Na^+ , Ba^+ , Cs^+ , Sr^{2+} , Pb^{2+}) to reside in the tunnel centers, whilst the B and C sites can accommodate a variety of di- tri- and pentavalent species such as Mg^{2+} , Cr^{3+} , Cu^{2+} , Zn^{2+} and Sb^{5+} (Lutze and Ewing, 1988). Zirconolite, prototypically $\text{CaZrTi}_2\text{O}_7$, is the most durable of the SYNROC phases, and is the primary tri- and tetravalent actinide-bearing host. The anion deficient fluorite superstructure of zirconolite permits substitution of tetravalent actinides U^{4+} , Pu^{4+} , and Th^{4+} for Ca^{2+} in eightfold coordination, alongside moderate substitution for Zr^{4+} and a range of di- tri- and pentavalent substitution for Ti^{4+} (e.g., Mg^{2+} , Fe^{3+} , Al^{3+} and Nb^{5+}). The structure of perovskite (ideally CaTiO_3) permits a wide array of Ca^{2+} substitution, including Sr^{2+} , Ba^{2+} , REE^{3+} , Cm^{3+} , and Pu^{3+} , hence is included in SYNROC primarily to uptake Sr and minor actinides. The partitioning of key HLW elements in the constituent SYNROC phases is summarized in Table 5. Comprehensive discussions of SYNROC mineralogy, fabrication and disposability are provided by (Ringwood, 1985; Lutze and Ewing, 1988).

Wasteloading: Wasteform chemistry should be tailored such that solubility of waste material in the host phase is as extensive as reasonably possible, without promoting the formation of deleterious secondary phases, or breaching criticality limits. This will alleviate GDF volume requirements through the reduction in the number of overall waste packages produced.

Chemical flexibility: The ideal immobilization matrix should demonstrate the ability to accommodate variations in feedstock chemistry without the formation of detrimental accessory phases that may compromise performance in the disposal environment. This may include fluctuations in processing contaminants and additives. Multiphase ceramic, or glass-ceramic composite materials may be preferable to single phase ceramic materials in this respect.

Synthesis: Wasteform processing should favor rugged and established processing techniques, promoting compatibility with existing technology. Where possible, exotic syntheses routes and high temperature thermal treatments should be avoided, so as to prolong the lifetime of equipment, and suppress the potential for volatilization. These processes should also consider the environmental and economic impact of any secondary effluents that may be produced.

Aqueous durability: Leaching of the wasteform matrix in saturated groundwater compositions is considered to be the primary mechanism by which radionuclides begin to migrate into the near field environment. The wasteform should exhibit high chemical durability under such conditions, with the formulation optimized in laboratory trials to ensure the leach resistance is maximized. The aqueous durability of the chosen wasteform may be established through a variety of field tests, establishing a measure of the corrosion rate. However, the selection of wasteforms with existing natural analogs is preferable, as these specimens provide a true measure of corrosion resistance under geological timescales, and therefore act as a useful reference to support the safety case for geological disposal.

Radiation tolerance: The wasteform should exhibit resistance against amorphization due to the effects of self-irradiation. The formation and accumulation of decay products within the bulk wasteform may impact the overall mechanical integrity of the waste package, leading to volume swelling and cracking. This may, in turn, decrease the long-term durability by increasing the available surface area available for leaching.

Table 5 Distribution of key HLW elements in SYNROC phases.

Hollandite	Zirconolite	Perovskite	Metal
Cs^+	U^{4+}	Na^+	Ru
Rb^+	Th^{4+}	Sr^{2+}	Tc
K^+	Pu^{4+}	Pu^{3+}	Mo
Ba^{2+}	Cm^{4+}	Am^{3+}	Ni
Fe^{2+}	Am^{4+}	Cm^{3+}	Pd
Cr^{3+}	Np^{4+}	Np^{3+}	Rh
Ni^{2+}	Sr^{2+}	—	Te
Mo^{4+}	—	—	S

Table 6 Mineralogy of various SYNROC formulations.

Formulation	Ideal mineral composition (wt.%)						
	Zirconolite	Hollandite	Rutile	Perovskite	Alloy phases	Spinel	Nepheline
SYNROC-C	30	30	15	20	5	—	—
SYNROC-D	19	3	—	15	—	46	17
SYNROC-E	7 ^a	5	79	7	—	—	—
SYNROC-F	90	5	5	—	—	—	—
SYNROC-Z	10	35	20	30	5	—	—

^aPlus approximately 2% pyrochlore.

The conventional method of SYNROC fabrication involves the addition of ~2% Ti metal, due to the reducing conditions imposed during hot pressing. As the oxidation of the Ti reduces some portion of the Ti^{4+} inventory to Ti^{3+} , rutile, and related Maggelli phases TiO_{2-n} are included to provide an excess of Ti^{4+} , thus preventing the stabilization of Ti-poor phases such as $CsAlTiO_4$ that may be detrimental to wasteform performance in the disposal environment (Ringwood, 1985). The mineralogy of SYNROC may be varied, such that the relative proportions of the host ceramic phases are tailored to complement specific waste-streams (Table 6).

For example, whereas SYNROC-C was developed for as an alternative to borosilicate glass as an immobilization matrix for HLW waste streams, SYNROC-D is a unique variation developed specifically for the immobilization of defense wastes produced at the Savannah River Plant, favoring the replacement of hollandite with nepheline, and an inert spinel phase. Confidence in the SYNROC approach as a viable alternative to glass was largely supported by field durability studies. Development work by (Oversby and Ringwood, 1981) compared the release rates of key elements from 0.5 g disks of SYNROC and PNL-76-68 borosilicate glass (loaded with 33% simulant HLW), at both 85 °C and 200 °C. Based the concentrations of Ca, Cs and U in the distilled H_2O leaching solution, it was determined that whilst the PNL-76-68 wasteform had average leach rates of 1.4 and 8.9 $g\ m^{-2}\ day^{-1}$ at 85 °C and 200 °C, respectively, the upper limit of the SYNROC leach rate was several orders of magnitude lower at $<0.005\ g\ m^{-2}\ day^{-1}$. Subsequent work by (Ringwood et al., 1981) confirmed that whilst the retention of Cs in SYNROC was 500 times greater than PNL-76-68 at 95 °C, over a period between 10 and 30 days, the leach rate of U from SYNROC was 10^5 times lower than for corresponding borosilicate formulations (Fig. 2). The long term durability of SYNROC has also been established, with monoliths of SYNROC-C containing 10 wt.% simulated PW-4b-D HLW, containing 0.62 wt.% ^{239}Pu subjected to leaching in deionized water at 70 °C for a total of 2472 days. The normalized release rate of Pu from these samples was observed to be $\sim 5 \times 10^{-5}\ g\ m^{-2}\ day^{-1}$ (Smith et al., 1997). The radiation stability of SYNROC wasteforms is largely informed by in situ (i.e., doping with short lived actinides such as ^{238}Pu) and/or ex situ (i.e., charged ion-irradiation or gamma/neutron irradiation) response testing of the constituent actinide

Fig. 2 Bulk leach rates of Cs and Ca from SYNROC and PNL-76-68 borosilicate glass. From Ringwood AE, et al. (1981) Immobilization of high-level nuclear reactor wastes in synroc: A current appraisal. *Nuclear Waste Management* 2: 287–305.

bearing phases, e.g., zirconolite and perovskite, which are discussed in the following sections. However, several pertinent examples of SYNROC radiation testing have been reported. For example specimens of SYNROC-C were subjected to neutron irradiation dose of $4.8 \times 10^{20} \text{ n cm}^{-2}$, corresponding to a simulated aging of 2×10^5 year (Woolfrey et al., 1982). Specimens remained physically intact, yet with micro-cracking observed at volume expansions $\geq 4\%$. The microstructure of SYNROC-C doped with ^{238}Pu and ^{244}Cm , with ages in excess of 20 years and estimated experienced dose of $3 \times 10^{19} \alpha \text{ g}^{-1}$, were characterized by (Hambley et al., 2008). Micro-cracking was present across hollandite and rutile-rich regions of the microstructure yet did not extend across regions of zirconolite-perovskite intergrowths. As Pu was exclusively located, as expected, in the zirconolite and perovskite phases, the resultant swelling of these grains was proposed as the cause for the cracking. For a comprehensive review of radiation effects in SYNROC, and related titanate phases, the reader is referred to (Weber et al., 1998).

Single phase wasteforms

Whilst the original motivation for ceramic wasteform development was to develop alternative matrices to conventional borosilicate glasses, for the conditioning of heterogeneous reprocessing wastes, the past several decades have seen some nations strengthen reprocessing efforts, affording greater quantities of separated Pu and other actinides. Moreover, strategic arms reductions between the United States and the former Soviet Union has afforded some 100 metric tonnes of Pu designated as waste for disposal. Hence, the nature of wasteform development has evolved to favor the study of designated single-phase ceramic materials as immobilisation matrices for high purity actinide inventories. This rationale has seen many crystalline phases proposed for actinides (Table 7), justified by high durability and radiation stability, informed by natural analogs and laboratory field tests. For brevity, we shall provide a brief discussion of the crystallography and chemical properties of the titanate phases: pyrochlore, zirconolite, brannerite and perovskite.

Pyrochlore ($\text{A}_2\text{B}_2\text{O}_7$)

The pyrochlore family of minerals conforming to $^{\text{VIII}}\text{A}_2^{\text{VI}}\text{B}_2^{\text{IV}}\text{X}_6^{\text{IV}}\text{Y}_1$ stoichiometry have been proposed as wasteforms for the immobilization of actinides, including Pu, either through solid solution with the 16(d) B^{4+} site e.g., $\text{Gd}_2\text{Ti}_{2-x}\text{Pu}_x\text{O}_7$ or replacement of the 16(c) A site e.g., $\text{CaPuTi}_2\text{O}_7$. The cubic pyrochlore structure (ideally $\text{A}_2\text{B}_2\text{O}_7$ —space group $\text{Fd}\bar{3}m$) is described as a defect fluorite superstructure, related to the ideal AX_2 fluorite unit cell with one eighth of the oxygen atoms replaced by ordered vacancies on the anion sublattice. Over 500 distinct compositional variations of this phase have been reported through control of A and B-site cations, hence single phase pyrochlore materials certainly offer the requisite structural flexibility to act as nuclear wasteforms for actinides. Typically, the A-site is able to incorporate formal valence states between +1 and +6, and the B-site between +3 and +6, although the mineralogy of pyrochlore typically favors the occupation of the eightfold coordinated A site with large tri- and tetravalent actinide and rare earth cations (e.g., Th^{4+} , U^{4+} , Gd^{3+} , Y^{3+} , Sm^{3+}) and smaller cation modifiers on the B-site (Zr^{4+} , Ti^{4+} , Ta^{5+} , Sb^{5+}). The long term durability of pyrochlore is supported by the existence of naturally altered specimens, many of which exist with primordial U/Th inventories, up to 30 wt.% and 9 wt.%, respectively, although the durability of these analogs is thought to be slightly lower than that of zirconolite (Lumpkin, 2001). Wang et al. (2019) tested the durability of $(\text{Gd},\text{Sm})_2(\text{Zr},\text{Ce})_2\text{O}_7$ pyrochlore materials through static leaching in distilled water for 7 day at 90°C , with the leaching rates of all elements between 10^{-6} and $10^{-7} \text{ g m}^{-2} \text{ day}^{-1}$. Icenhower et al. (2000) investigated the corrosion resistance of $\text{Lu}_2\text{Ti}_2\text{O}_7$ and $\text{Gd}_2\text{Ti}_2\text{O}_7$ through dissolution under dynamic SPFT conditions at $\text{pH} = 2$, confirming that even at under highly acidic conditions, dissolution rates remained low, in the range 1.3×10^{-3} – $7.0 \times 10^{-4} \text{ g m}^{-2} \text{ day}^{-1}$. The stability and radiation response of pyrochlore-structured phases is dictated by the relative size ratio of A and B-site cations, with the cubic-forming region determined experimentally to be $1.46 < r_A/r_B < 1.78$. Compositions for which $r_A/r_B < 1.46$ form destabilize to form the defect fluorite structure, in which A and B-site cations become randomly distributed, and oxygen vacancies become disordered along the anion sublattice (Lang et al., 2010). (Reid et al., 2012) synthesized the $\text{Gd}_2\text{Zr}_{2-x}\text{Ce}_x\text{O}_7$ with the view to simulate Pu^{4+} immobilization, identifying three distinct phases corresponding to pyrochlore ($x < 0.25$), defect fluorite ($0.5 < x < 0.75$) and an incommensurate C*-type structure for $x = 1.00$. The response to radiation is significantly improved for Zr based pyrochlores, as is shown in Fig. 3 for the $\text{Gd}_2\text{Ti}_{2-x}\text{Zr}_x\text{O}_7$ binary system.

Table 7 Candidate ceramic wasteforms for actinide immobilization.

Ceramic phase	Ideal formula	Space group	Unit cell parameters ($\text{\AA}$, $^\circ$)	Calculated density (g cm^{-3})
Zirconolite	$\text{CaZrTi}_2\text{O}_7$	C2/c	$a = 12.44$; $b = 7.27$; $c = 11.38$; $\alpha = \gamma = 90$; $\beta = 100.56$	4.44
Pyrochlore (Zr)	$\text{Gd}_2\text{Zr}_2\text{O}_7$	Fm $\bar{3}m$	$a = b = c = 5.27$; $\alpha = \beta = \gamma = 90$	6.91
Pyrochlore (Ti)	$\text{Gd}_2\text{Ti}_2\text{O}_7$	Fd $\bar{3}m$	$a = b = c = 10.18$; $\alpha = \beta = \gamma = 90$	6.57
Zirconia	ZrO_2	P2 $_1$ /c	$a = 4.15$; $b = 5.21$, $c = 5.32$, $\alpha = \gamma = 90$; $\beta = 99.21$	5.82
Zircon	ZrSiO_4	I4 $_1$ /amd	$a = b = 6.60$; $c = 5.98$; $\alpha = \beta = \gamma = 90$	4.66
Monazite	CePO_4	P2 $_1$ /c	$A = 6.77$; $b = 7.00$; $c = 6.44$; $\alpha = \gamma = 90$; $\beta = 103.42$	5.26
Xenotime	YPO_4	I4 $_1$ /amd	$a = b = 6.89$; $c = 6.03$; $\alpha = \beta = \gamma = 90$	4.26
Brannerite	UTi_2O_6	C2/m	$a = 9.81$; $b = 3.77$; $c = 6.93$; $\alpha = \gamma = 90$; $\beta = 118.96$	6.36
Kosnarite	$\text{KZr}_2(\text{PO}_4)_3$	R3c	$a = b = 8.73$; $c = 23.20$; $\alpha = \beta = 90$; $\gamma = 120$	4.38
Perovskite	CaTiO_3	Pbnm	$a = 5.38$; $b = 5.44$; $c = 7.64$; $\alpha = \beta = \gamma = 90$	4.04

Fig. 3 Dependence of amorphisation dose rate on x parameter in $Gd_2Ti_{2-x}Zr_xO_7$ pyrochlore (A) and choice of REE $^{3+}$ cation (B). Reproduced from Ewing RC, Weber WJ and Lian J (2004) "Nuclear waste disposal-pyrochlore ($A_2B_2O_7$): Nuclear waste form for the immobilization of plutonium and 'minor' actinides". *Journal of Applied Physics* 95(11): 5949–5971, with the permission of AIP Publishing.

Zirconolite ($CaZrTi_2O_7$)

Zirconolite, nominally $CaZrTi_2O_7$, is a relatively rare accessory mineral located in a variety of geological formations, and is included as the primary actinide bearing phase in the SYNROC wasteform. However, in recent years there has been a renewed interest in the development of single phase zirconolite ceramic materials for the immobilization of stockpiled Pu inventories, and zirconolite glass-ceramic composites for the conditioning of Pu residues, in the United Kingdom. Zirconolite has a demonstrated affinity for extensive substitution of several actinides ($Pu^{3+/4+}$, Np^{3+} , $U^{4+/6+}$, Th^{4+}), rare earth (Y^{3+} , Sm^{3+} , Nd^{3+} , Gd^{3+}) and alkaline/transition (Mg^{2+} , Al^{3+} , Fe^{3+} , Cr^{3+}) elements. Zirconolite, related to $A_2B_2O_7$ pyrochlore by a compression along the (111) plane, is an anion deficient fluorite-type structure, with cation ordering on planes parallel to the superstructure c -axis. A projection of the zirconolite unit cell is displayed in Fig. 4. The zirconolite-2M parent structure, stabilized over the compositional range $CaZr_xTi_{3-x}O_7$ ($0.8 < x < 1.3$), crystallizes with monoclinic symmetry in the space group ($C2/c$, $Z = 8$). The unit cell forms a lamellar structure comprised of alternating layers of Ca^{2+}/Zr^{4+} polyhedra, coordinated eight- and sevenfold to oxygen, respectively, interspaced 1:1 along the (001) plane with sheets of Ti^{4+} octahedra arranged in a hexagonal tungsten bronze (HTB) type topology.

Ti^{4+} is present in three distinct crystallographic sites, two of which, Ti(I) and Ti(III), are contained in sixfold coordination, whilst Ti(II) forms an unusual trigonal bipyramidal TiO_5 site, located off-center from the six membered ring, statistically 50% occupied. The chemistry of zirconolite permits solid solution of actinides and charge compensator species across the five distinct cation receptor sites ^{VIII}Ca , ^{VII}Zr , $^{VI}Ti(I)$, $^{VI}Ti(II)$ and $^{VI}Ti(III)$, and hence allows for accommodation of multiple cations in conjunction. Several substitution regimes have been proposed and demonstrated for both tri- and tetravalent actinide species. For example, (Begg et al., 2001)

Fig. 4 Crystal structures of zirconolite-2M, 4M and 3T polytypes.

demonstrated that Pu^{4+} may be accepted in solid solution via isovalent substitution for Zr^{4+} , i.e., $\text{CaZr}_{1-x}\text{Pu}_x\text{Ti}_2\text{O}_7$. Alternatively, it has been demonstrated that heterovalent tri- and tetravalent substitution for Ca^{2+} is also feasible, with a lower valence charge balancing species such as Al^{3+} accommodated across Ti^{4+} sites, e.g., $\text{Ca}_{1-x}\text{Pu}_x\text{ZrTi}_{2-2x}\text{Al}_{2x}\text{O}_7$ and $\text{Ca}_{1-x}\text{Pu}_x\text{ZrTi}_{2-x}\text{Al}_x\text{O}_7$ for Pu^{4+} and Pu^{3+} , respectively (Vance et al., 1994). The progressive substitution of foreign elements, depending on the chosen substitution regime and processing conditions, has been shown to stabilize a variety of crystallographically distinct polytype variants of zirconolite, most notably zirconolite-4M and zirconolite-3T (formerly recognized as zirkelite (Bayliss et al., 1989)). Successive zirconolite polytypes are characterized by variations in stacking sequence of Ca/Zr and HTB layers. For example, the structure of zirconolite-4M resembles intergrowths of zirconolite-2M and pyrochlore-type modules, resulting in lattice expansion along the c-axis and stacking of four Ca/Zr—HTB interlayers to comprise the unit cell. Isovalent substitution of U^{4+} , Ce^{4+} and Pu^{4+} for Zr^{4+} targeting $\text{CaZr}_{1-x}(\text{Ce}, \text{U}, \text{Pu})_x\text{Ti}_2\text{O}_7$ has been shown to favor zirconolite-4M as the dominant actinide phase above a threshold of $x = 0.15$, with further substitution to $x = 0.50$ yielding the pyrochlore phase (Begg et al., 2001; Vance et al., 2002; Blackburn et al., 2020a). Interestingly, it was recently reported that the $\text{CaZr}_{1-x}\text{Th}_x\text{Ti}_2\text{O}_7$ did not give rise to the zirconolite-4M intermediate phase, rather a Th-rich pyrochlore phase was preferred in the interval $0.10 \leq x \leq 0.50$, forming a single phase at $x = 0.60$ (Blackburn et al., 2021). Targeting tetravalent substitution for Ca^{2+} , coupled with a charge balancing species has been shown to extend the formation range of zirconolite-2M. For example, (Vance et al., 2002) confirmed the formation of single phase 2M when targeting $\text{Ca}_{0.80}\text{U}_{0.20}\text{ZrTi}_{1.60}\text{Al}_{0.40}\text{O}_7$, with complementary data by (Deschanel et al., 2006) targeting, $\text{Ca}_{0.87}\text{Pu}_{0.13}\text{ZrTi}_{1.73}\text{Al}_{0.30}\text{O}_7$ confirming the 2M structure. Using Ce as a surrogate, (Blackburn et al., 2020b) confirmed the 2M polytype could be stabilized up to $x = 0.35$ in the $\text{Ca}_{1-x}\text{Ce}_x\text{ZrTi}_{2-2x}\text{Cr}_{2x}\text{O}_7$, however, partial Ce^{3+} speciation promoted the formation of a Ce-rich perovskite phase. Furthermore, (Gilbert et al., 2010) reported the formation of the 3T polytype for the corresponding $\text{Ca}_{1-x}\text{Pu}_x\text{ZrTi}_{2-2x}\text{Fe}_{2x}\text{O}_7$ solid solution. Incorporation of trivalent actinide species may be accomplished through equimolar substitution of a trivalent charge balancing species such as Al^{3+} , extending the solid solution range over which the zirconolite-2M polytype is stabilized. For example, the $\text{Ca}_{1-x}\text{Nd}_x\text{ZrTi}_{2-x}\text{Al}_x\text{O}_7$ solid solution was fabricated by Ma et al., confirming that zirconolite-2M remained single phase for $x \leq 0.6$, after which the orthorhombic zirconolite-3O polytype was produced (Ma et al., 2018). The radiation stability of zirconolite is comparable to that of $\text{Gd}_2\text{Ti}_2\text{O}_7$ through doping with 3 wt.% ^{244}Cm (Weber, Wald and Matzke, 1986), with an amorphisation dose corresponding to $0.47 \times 10^{16} \alpha \text{ mg}^{-1}$ causing bulk swelling between 6–6.5 vol.%. Similar results have been reported by ion irradiation with $1.3 \times 10^{21} \text{ keV cm}^{-1} \text{ Au}^+$ (Deschanel et al., 2014). A comprehensive report on the radiation response of zirconolite was provided by (Strachan et al., 2008), concluding that a dose rate of $2.6 \times 10^{18} \alpha/\text{g}$ was necessary to amorphize ^{238}Pu doped zirconolite. Furthermore, the forward dissolution rate at $\text{pH} = 2$ was experimentally determined as $1.7 \times 10^{-3} \text{ g m}^{-2} \text{ day}^{-1}$, showing no dependence on the amount of induced radiation damage. Other studies have concluded that the leaching of elements is not affected by amorphisation, whereas the release rates from fully amorphous pyrochlore specimens, have in some instances, been shown to increase by a factor of 10–15 (Smith et al., 2003). Durability studies have demonstrated that release rates of actinide surrogates from zirconolite specimens are typically of the order $10^{-6} \text{ g m}^{-2} \text{ day}^{-1}$. Zhang et al. (2017) determined that the release of Ce from monoliths of zirconolite, with nominal composition $\text{CaZr}_{0.70}\text{Ce}_{0.30}\text{Ti}_2\text{O}_7$, was as low as $2.3 \times 10^{-6} \text{ g m}^{-2} \text{ day}^{-1}$ over a 42 day period in deionized H_2O . Similar results were reported by (Wen et al., 2015) with Ce leach rates of $2.3 \times 10^{-6} \text{ g m}^{-2} \text{ day}^{-1}$ over a 28 day period. Exceptionally low Gd^{3+} release rates of $4.72 \times 10^{-7} \text{ g m}^{-2} \text{ day}^{-1}$ were recently reported by Zhang et al. (2019) from $\text{Ca}_{1-x}\text{Hf}_{1-x}\text{Gd}_x\text{Ti}_2\text{O}_7$ zirconolite, with Gd included as a trivalent actinide surrogate. A summary of pH dependent U leaching from zirconolite, relative to other candidate wasteforms, was provided by Weber et al. (2009) and is summarized in Fig. 5.

Fig. 5 Summary of U release rates ($\text{g m}^{-2} \text{ day}^{-1}$) from a selection of candidate wasteforms. From Weber WJ, Navrotsky A, Stefanovsky S, Vance ER, and Vernaz E (2009) Materials science of high-level nuclear waste immobilization. *MRS Bulletin* 34 (01): 46–52.

Brannerite (UTi₂O₆)

Brannerite is a common accessory U-bearing accessory mineral, with a prototypical composition of UTi₂O₆, and in some areas is the principle uranium ore. As natural brannerites contain ~55 wt.% U, ceramics based on the UTi₂O₆ system may be suitable hosts for wastes containing a high fraction of actinides, such as MOX residues (Bailey et al., 2018). UTi₂O₆ is a layered structure comprised of anatase-type sheets of edge-sharing distorted TiO₆, with chains of edge-sharing UO₆ octahedra connecting adjacent Ti-O layers. The ideal UTi₂O₆ structure crystallizes in monoclinic symmetry (space group C2/m) and is only formed under low partial oxygen pressure, in order to maintain U⁴⁺ valence. The preparation of UTi₂O₆ in air, to the correct stoichiometry, has been shown to produce a mixture of U₃O₈ and TiO₂. The U⁴⁺ site can be completely replaced by isovalent Ce/Th substitution, e.g., the isostructural thorutite structure ThTi₂O₆, however, the counterpart Ce brannerite was shown to be non-stoichiometric, viz Ce_{0.975}Ti₂O_{5.95}, with cerium and oxygen vacancies, as determined by powder neutron diffraction (Stennett et al., 2012). The incorporation of higher valence actinide species in brannerite is permitted through the co-substitution of lower valence charge balance species. For example, U_{1-x}Y_xTi₂O₆ and Th_{1-x}Y_xTi₂O_{6-δ} solid solutions were synthesized in air at 1400 °C by (James et al., 2003) and it was determined that the accommodation of Y³⁺ was greater in UTi₂O₆, due to the formation of charge balancing U⁵⁺ centers. Y³⁺ accommodation in ThTi₂O₆ is considerably lower, permitted by the formation of oxygen vacancies due to the stability of Th⁴⁺ in air. The chemical durability of brannerite is consistently lower than that of related zirconolite and pyrochlore phases, yet 3–4 orders of magnitude more durable than some glass matrices. Amorphous specimens of natural brannerite from the El Cabril mine (Spain) have been recrystallized by annealing at a range of temperatures by (Zhang et al., 2006) prior to durability testing. U release rates in weakly acid conditions (pH = 4) at 30 °C were observed to be ~1 × 10⁻³ g m⁻² day⁻¹ when annealed at 500 °C. Synthetic UTi₂O₆ was produced and dissolved over the pH range 2–12 by (Roberts et al., 2000) at 25 °C, 50 °C and 75 °C. The dissolution rate increased with temperature, yet the magnitude of the increase was observed to vary with pH, reaching a minimum near pH = 8. Whilst the dissolution rates for brannerite were in some instances a factor of 30 greater than zirconolite under the same conditions, the release rates for U were moderately low, between 10⁻³ and 10⁻⁵ g m⁻² day⁻¹. Nevertheless, brannerite may act as a buffer phase to accommodate excess actinides that may exceed the solubility limit in targeted phases, and its inclusion not expected to significantly impact the overall performance of wasteform materials for actinides in the geological environment.

Perovskite (CaTiO₃)

Perovskite (ABO₃) structured materials are extensively studied, and have a wide field of applications, particularly in the development of photonic functional materials, and as a primary constituent of the SYNROC wasteform. Oxide perovskites have the general structure ABO₃, in which BO₆ octahedra form a three-dimensional corner sharing framework, with large A-site cations (i.e., Ca²⁺, Sr²⁺) residing in the cavity, 12-fold coordinated with oxygen. Although ABO₃ perovskites ideally have cubic symmetry in the Pm-3m space group, most perovskites are distorted due to tilting of BO₆ octahedra, caused by variation in cation radii r_A and r_B, and may undergo reversible, phase dependent transitions. For example, the CaTiO₃ unit cell distorts with orthorhombic symmetry in the space group Pbnm at room temperature, to tetragonal I4/mcm at 1225 °C, with a further transition to cubic Pm-3m observed at 1361 °C. The binary system Ca_{1-x}Sr_xTiO₃ exhibits complete solid solubility, with a structural transformation from Pbnm to the I4/mcm structure at x = 0.6, followed by transformation to Pm-3m with additional Sr²⁺ content (Qin et al., 2002). CaTiO₃ has been proposed as a host phase for Pu³⁺ and Pu⁴⁺ due to high radiation tolerance. (Ca_{0.9}Nd_{0.1})(Ti_{0.9}Al_{0.1})O₃ was synthesized by (Davoisne et al., 2011) with Nd³⁺ employed as a structural simulant for Pu³⁺, and irradiated with a dose of 2 MeV Kr⁺ at 5 × 10¹⁵ ions cm⁻² with the view to simulate Pu recoil damage during α-decay. A well-defined damage region of 0.8–1.1 μm was observed, however only some of this was amorphous; the number of displacements per atom (dpa) was estimated at around 4 dpa (Fig. 6).

The incorporation of Ce³⁺ and Ce⁴⁺ within the CaTiO₃ was investigated by (Begg et al., 1998b) with Ce acting as a structural simulant for Pu. Ce³⁺ was successfully incorporated within the Ca²⁺ site with Al³⁺ charge compensation targeting Ca_{0.9}Ce_{0.1}Ti_{0.9}Al_{0.1}O₃ under both oxidizing and reducing conditions, with the partial formation of Ce⁴⁺ formed in air charge balanced by Ti⁴⁺ vacancies. Ce⁴⁺ was fully accommodated into single phase when targeting Ca_{0.9}Ce_{0.1}Ti_{0.8}Al_{0.2}O₃ under oxidizing conditions, however Ce was distributed as 80% Ce⁴⁺, with the excess negative charge apparently compensated by oxygen vacancies. Moreover, Ce³⁺ was fully accommodated into single phase Ca_{0.9}Ce_{0.1}TiO₃ with lower valence species available for charge compensation, demonstrating the formation of cation vacancies. These solid solutions were later verified by (Begg et al., 1998a), using Pu^{3+/4+}, in all instances minor undigested PuO₂ (< 2%) was evidenced. Investigations of Pu incorporation within Ca_{0.9}Pu_{0.1}Ti_{0.9}Al_{0.1}O₃ (targeting Pu³⁺), Ca_{0.9}Pu_{0.1}Ti_{0.8}Al_{0.2}O₃ (targeting Pu⁴⁺) and Ca_{0.9}Pu_{0.1}TiO₃ (targeting Pu³⁺) yielded near single phase perovskite when sintering in air, with Pu uniformly present as Pu⁴⁺; annealing in 3.5% H₂/N₂ resulted in 80–90% Pu³⁺ and the subsequent formation of a minor CaPu(Ti,Al)₂O₇ pyrochlore, at ~2 wt.% in each instance. The preferential incorporation of Ce within the CaTiO₃ phase is likely the result of increased reduction potential with respect to Pu, although the extent of Pu solubility on the Ca site has not been explicitly determined. CaTiO₃ has also demonstrated the ability to successfully accommodate both Np in both Np³⁺ and Np⁴⁺ valence states through tailoring the oxygen fugacity during synthesis (Begg et al., 1998a). Similar to related Pu compositions, targeting Np³⁺ incorporation in the absence of charge balancing additives did not prevent the formation of near single phase Ca_{0.90}Np_{0.10}TiO₃ when reacting in both air and 5% H₂/N₂. Np⁴⁺ remained the dominant valence state when targeting Ca_{0.90}Np_{0.10}Ti_{0.80}Al_{0.20}O₃ regardless of the sintering atmosphere, yielding >99% perovskite, demonstrating the ability of the phase to successfully immobilize both tri- and tetravalent actinides. The fundamental disadvantage hindering the deployment of single phase perovskite as an actinide wasteform pertains to its aqueous durability. Despite greater radiation tolerance relative to the actinide-designated zirconolite

Fig. 6 TEM micrograph of damage region of Nd-doped perovskite irradiated with 2 MeV Kr⁺ at a dose of 5×10^{15} ions cm⁻², detailing a well-defined damage region between 0.8–1.1 μm, in agreement with TRIM calculations. From Davoisne C, Stennett MC, Hyatt NC, Peng N, Jeynes C, and Lee WE (2011) Krypton irradiation damage in Nd-doped zirconolite and perovskite. *Journal of Nuclear Materials* 415 (1): 67–73.

phase, perovskite is considered the most soluble of the SYNROC phases under hydrothermal conditions. Durability tests on disks of well characterized SYNROC-C in de-ionized water, bicarbonate and silicate solutions saturated at 150 °C up to 84 days confirmed that the dissolution rates of the SYNROC phases followed the order perovskite > hollandite > zirconolite, with the percentage of initial Al, Ca and Ce distributed across the SYNROC phases released after 337 days in 150 °C deionized water determined to be 0.10%, 0.068% and 0.045%, respectively (Lumpkin et al., 1991; Smith et al., 1992). Given the lower relative durability of perovskite with respect to zirconolite, and the common presence of CaTiO₃ as an ancillary phase during zirconolite synthesis, it is often desirable to reformulate precursor compositions with an excess of ZrO₂ and TiO₂ to preclude the ingrowth of perovskite.

Summary

Actinides, once chemically partitioned and separated from nuclear reactor wastes, pose an acute security and proliferation risk when stored *en masse* as unirradiated inventories. A credible pathway towards actinide disposition is immobilization in dedicated ceramic matrices, the design of which is largely informed by the study of naturally occurring mineral analogs that are robust against geological weathering. The SYNROC approach to wasteform development, comprised of durable titanate crystalline phases each targeting specific radionuclides present in HLW waste streams, demonstrated that ceramic immobilization is a feasible pathway to disposition, whilst offering superior aqueous durability compared to conventional borosilicate glass wasteforms under a range of standardized corrosion tests. A wide variety of titanate, zirconate and silicate-based mineral species have since been proposed as single phase wasteforms for separated actinides, including zirconolite, pyrochlore, perovskite and brannerite. The chemistry of these materials permits solid solution with actinides, allowing waste cations to adopt the properties of the host lattice, thus stabilizing and solidifying the waste prior to geological disposal, alleviating difficulties associated with storage, transport and nuclear non-proliferation. Wasteform selection trials, commonly utilizing actinide surrogates with similar chemistry, are fundamental in underpinning this approach, with rare-earth (Ce^{3+/4+}, Gd³⁺, Sm³⁺, Eu³⁺) and in some cases U⁴⁺ and Th⁴⁺ commonly deployed as simulants. It should be noted, however, that with the exception of recent advances in the SYNROC program, the deployment of ceramic wasteform technology has not been demonstrated at the industrial scale. For example, whilst it is envisaged that ceramic matrices will be utilized to immobilize some portions of the United Kingdom Pu stockpile, there is still considerable development of industrial-scale processes necessary before such a program can be implemented.

Main features of ^{233}U and impact on spent Th-fuel properties

The thorium fuel cycle is a nuclear fuel cycle that uses an isotope of thorium, ^{232}Th , as the fertile material (IAEA, 2005). In the reactor core, ^{232}Th is transmuted into the fissile artificial uranium isotope ^{233}U by absorbing neutrons as shown in Fig. 1. Compared with ^{239}Pu and ^{235}U in U-Pu fuel cycle, main differences arising from ^{233}U in Th-U fuel cycle are:

- **Lacking fissile element ^{233}U in nature.** Being different from natural uranium, which contains $\sim 0.7\%$ 'fissile' ^{235}U isotope, natural thorium is made up only of the 'fertile' ^{232}Th isotope and does not contain any 'fissile' material. Therefore, thorium and thorium-based fuel in the form of metal, oxide or carbide, molten salt, et al., has been utilized in combination with 'fissile' ^{235}U or ^{239}Pu in power reactors for conversion to 'fissile' ^{233}U , thereby enlarging the 'fissile' material resources (IAEA, 2005; Yu et al., 2019; Zou et al., 2018a).
- **Less sensitive to neutron spectrum.** Unlike ^{235}U and ^{239}Pu , the number of neutrons released per neutron absorbed (represented as η) of 'fissile' ^{233}U nuclei is greater than 2.0 over a wide range of neutron spectrum as displayed in Fig. 2. The ^{232}Th - ^{233}U fuel cycle is hence less sensitive to the type of reactors, thermal or fast reactor (IAEA, 2005).
- **Less production of transuranic (TRU) isotopes.** Under thermal neutron flux, the capture cross-section of ^{233}U is much smaller (46 b) than those from ^{235}U (101 b) and ^{239}Pu (271 b), while all the three fissile isotopes have fission cross-section in the same order of magnitude (525, 577 and 742 b for ^{233}U , ^{235}U and ^{239}Pu , respectively). Therefore, it is much less probable to have non-fissile absorption with ^{233}U which would lead to higher isotopes (e. g., transuranic) with higher absorption cross-sections (Wu et al., 2019; Zou et al., 2015).
- **Other long term radionuclides.** ^{232}Th - ^{233}U fuel cycle produces much less plutonium and minor actinides like Np, Am and Cm than that of U-Pu fuel cycle, but is associated with other long term radionuclides such as ^{231}Pa (half-life of $\sim 34,300$ years) (Winkle et al., 1949), ^{229}Th (half-life of ~ 7340 years) (Britannica, n.d.) and ^{230}Th (half-life of $\sim 75,381$ years) (Meadows et al., 1980).
- **^{233}Pa problem.** ^{233}Pa is formed as an intermediate in the conversion chain of ^{232}Th to ^{233}U . It has a relatively longer half-life (~ 27 days) as compared to its counterpart ^{239}Np (half-life of ~ 2.4 days) in the uranium fuel cycle. As a consequence, to complete the decay of ^{233}Pa to ^{233}U and avoid loss of any ^{233}U fissile material, at least 12 months (more than 10 half-lives of ^{233}Pa) is required for cooling prior to reprocessing (OECD-NEA, 2015a).
- **^{232}U problem.** ^{232}U is produced along with the bred ^{233}U in irradiated mixed ^{232}Th - ^{233}U fuel. The $^{233}\text{Pa}(n,2n)^{232}\text{Pa}(\beta^-)^{232}\text{U}$ and $^{233}\text{U}(n, 2n)^{232}\text{U}$ reaction with the neutron energy threshold up to ~ 6.37 MeV are two main ways of generating ^{232}U . ^{232}U decays into ^{228}Th by emitting alpha particles and has a half-life of 73.6 years. Radiation hazard mainly arises due to build-up of the gamma emitting, short-lived daughter products of ^{228}Th , namely ^{212}Pb , ^{212}Bi and ^{208}Tl , particularly ^{208}Tl , which emits 2.6 MeV gamma radiation (OECD-NEA, 2015b).

Table 1 lists the specific radiation rates for main actinides in thorium fuel cycle and uranium cycle. Main differences arising from ^{232}U and ^{233}U in thorium-based fuel cycle would impact the properties of spent Th-fuel, including the radioactivity and toxicity, which in turn influence the nonproliferation, spent fuel reprocessing and disposal (IAEA, 2005).

- **Impact on reprocessing of spent Th-based fuels.** THORium-uranium EXtraction (THOREX) process (as shown in Fig. 3), which is the wet chemical route developed in Oak Ridge National Laboratory (ORNL) in the mid 1950s based on solvent extraction separation of uranium and thorium from fission products by means of tributyl phosphate (TBP) (Gresky, 1956), is so far the most viable route for recovery of uranium from spent Th-based fuels. Up to now, reprocessing of spent thorium fuel has been carried out only in a few countries (Merz, 1982) based on THOREX process mostly on laboratory or pilot plant scale. In the THOREX process, Pa is generally passed into the fission product waste, which could have long term radiological impact due to the formation of ^{231}Pa . High gamma emitters ^{232}U and ^{228}Th cannot be chemically separated from the recovered ^{233}U and thorium respectively. The formed high-energy gamma radiation field requires remote reprocessing and refabrication of Th-based

Fig. 1 Main isotopes in ^{232}Th - ^{233}U fuel cycle (IAEA, 2005). From IAEA (2005) *Thorium Fuel Cycle-Potential Benefits and Challenges*. IAEA-TECDOC-1450.

fuels. In addition, off-gas transport of the highly radioactive radon daughters through high-efficiency particulate air (HEPA) filters to the environment should be avoided in reprocessing spent fuel (for recovery and recycle of ^{233}U). It is necessary to withhold the off-gas around 10 min in designing the off-gas system to allow for decay of ^{220}Rn prior to HEPA filtration. The above issues also exist in the pyrochemical route of spent thorium fuel reprocessing, which is still in laboratory level. If thorium is not to be recycled because of its radioactivity, its disposal becomes an additional problem.

- *Impact on non-proliferation of spent Th-based fuels.* The high energy gamma ray emitted by the daughter products of ^{232}U could help to detect ^{233}U , which, from the standpoint of safeguards (i.e. the means to prevent unauthorized use of ^{233}U), is an asset (Wu et al., 2020).
- *Impact on radiotoxicity evolution of spent Th-based fuels.* A pure $\text{Th}/^{233}\text{U}$ cycle will indeed produce a much reduced amount of transuranics than conventional UO_2 fuels. But, decay products from ^{233}U (^{229}Th with the half-life of 7340 years) and ^{234}U which is mainly produced through neutron capture on ^{233}U (^{226}Ra with the half-life of 1600 years) drive radiotoxicity to be higher than that of low enriched uranium or U/Pu fuel at around 10^5 years.

Evolution of Th-spent nuclear fuel radioactivity and toxicity with time

Radiotoxicity, caused by the decay of fission products and actinides, is an important parameter in fuel cycle consideration, wherever spent fuel is disposed of (Clement, 2012). The radiotoxicity from the spent fuel is mainly composed of two parts: (1) The fission products whose half-lives vary from days to over 200,000 years dominate the radiotoxicity in the first 500 years; (2) The long-term (of the order of about 10^3 – 10^6 years) radioactive hazard is dominated by plutonium and minor actinides (ICRP, 1995). In general, the period between 500 years and 10,000 years is considered to be an important factor in repository performance, because this period is the point when waste packages are likely to start losing their integrity and subsequently release radionuclides in the near-field environment. After this period, most of the fission products have decayed and the radiotoxicity becomes dominated mainly by transuranic elements.

Typically for the Th-U fuel cycle, the radiotoxicity evolution of spent nuclear fuel can be divided into three main phases due to the radioactive decay of spent nuclear fuel (as shown in Fig. 4) (Brian et al., 2013):

- 1) 1–200 years: the medium-lived fission products dominate the radiotoxicity of the spent fuel. The fission product yields of ^{233}U are similar to ^{235}U and ^{239}Pu , and therefore the total radiotoxicity has little difference in this period. For the fission products, ^{90}Sr accounts for essentially all of the total radiotoxicity during this period for two reasons: (1) the 28.8-year half-life of ^{90}Sr is sufficiently long to allow it to contribute substantially to the radioactivity in this time period; (2) it has a relatively high radiotoxicity. The fission product yield of ^{90}Sr from ^{233}U (6.9%) is larger than the yield from ^{235}U (5.9%) (Croff and Krahn, 2016). Therefore, the radiotoxicity of the Th-based fuel is about twice that of the U-based fuel during this period.
- 2) 200–1000 years: the transuranics (primarily Np, Pu, Am, and Cm) dominate the radiotoxicity of the spent fuel in this period. In the thorium fuel cycle, five captures in ^{232}Th are necessary to produce a transuranic element. Therefore, the transuranic

Fig. 4 Ingestion radiotoxicity of Th-spent nuclear fuel (Thomas, 2017). From Yoshioka R, Kinoshita M, Takaki N, and Yoshida T (2015) Radiotoxicity evaluation for spent thorium fuel in PWR. *Transaction of AESJ-2015 Meeting, Hitachi, Japan*.

Fig. 5 Radiotoxicity for U-core and Th-core (Thomas, 2017). From Yoshioka R, Kinoshita M, Takaki N, and Yoshida T (2015) Radiotoxicity evaluation for spent thorium fuel in PWR. *Transaction of AESJ-2015 Meeting, Hitachi, Japan*.

production is extremely low. In addition, 98–99% of thorium-cycle fuel nuclei would fission as either ^{233}U or ^{235}U , so much fewer long-lived transuranics are produced (IAEA, 2005; Wikipedia, n.d.). Therefore, there are much lower quantities of plutonium and the longer-lived minor actinides compared with the uranium-plutonium (U-Pu) fuel cycle, typically several orders of magnitude less than the equivalent U-Pu fuel. The radiotoxicity in the Th-U fuel cycle in this period is therefore about 10 times lower than of the U-Pu fuel cycle (as shown in Fig. 5) (Thomas, 2017). In the back end of the thorium fuel cycle, the radiotoxicity of actinides of spent Th-U fuel is determined by ^{232}U and its daughter nuclides, the first of which is ^{228}Th , for the first 300 years. The half-lives of ^{232}U and ^{228}Th are 68.9 years and 1.9 years, respectively. The subsequent daughter nuclides in the decay chain of ^{232}U have shorter half-lives. The most significant of the remaining actinides are ^{238}Pu and ^{234}U , whose contributions are 10–100 times smaller. The contribution of ^{239}Pu , ^{240}Pu , ^{241}Am , and ^{232}Th is 104 times smaller than that of ^{232}U . After 100 years of storage, the total radiotoxicity decreases by a factor of 2.6 (Croff and Krahn, 2016).

- 3) > 1000 years: long-lived ^{233}U daughter products dominate the radiotoxicity in this period. For a disposal period longer than 1000 years, ^{232}U with its daughter nuclides do not contribute to the radiotoxicity, which is determined by ^{234}U and ^{230}Th . After 3000 years, the radiotoxicity increases because of the accumulation of ^{226}Ra , ^{229}Th , and ^{230}Th . When the disposal period is longer than 10,000 years, the radiotoxicity is determined by ^{226}Ra and ^{229}Th , and ^{233}U makes a small contribution. For a disposal period of 10,000 years, the radiotoxicity decreases by a factor of 160 relative to that at 1 year after shutdown (Bergel et al., 2001; Yoshioka et al., 2015). The dominance of these nuclides results in the radiotoxicity of the Th-U fuel cycle being about twice that of the equivalent U-Pu fuel cycle for these extended periods, although this can vary depending on the specific scenarios chosen.

The thorium cycle can fully recycle actinide wastes and only emit fission product wastes, and after a few hundred years, the waste from a thorium reactor can be less radiotoxic than the uranium ore that would have been used to produce low enriched uranium

fuel for a light water reactor of the same power. Therefore, the thorium fuel cycle can minimize the radiotoxicity associated with spent fuel and control radiotoxicity between 500 and 100,000 years (WNA, World Nuclear Association, 2009; Thorium Test Begins, n.d.). For example, in the closed thorium fuel cycle in fast reactors with Pu and minor actinides, the amount of Pu burning will be much larger relative to fast reactors operating with the U-Pu fuel cycle, and appreciable amounts of ^{233}U would be produced which could be utilized for starting new thorium-fueled thermal reactors or Accelerator Driven Systems (ADS) cycle (Croff and Krahn, 2016; Hesketh and Thomas, 2013; Abderrahim and Bruyn, 2021). Molten salt reactors with thorium fuel cycle have the unique advantages of online reprocessing (Zou et al., 2018a, b). If reprocessing is applied for MSR and most actinides such as U, Th, and their daughters are separated and recycled, then radiotoxicity after several hundred years can be greatly reduced (Yu et al., 2019; Zou et al., 2015; Robertson, 1971). The amount of radioactive waste produced by the thermal reactors based on Th-U fuel cycle is much less than that produced by PWRs with an once-through fuel cycle, and it also has obvious advantages compared with the fast breeder reactors based on U-Pu fuel cycle.

Key issues associated with Th-fuel processing and industrial experience

Molten salt reactors are particularly well adapted to the ^{232}Th - ^{233}U fuel cycle which has the advantage of producing less minor actinides than the ^{238}U - ^{239}Pu fuel cycle. Moreover, the Th- ^{233}U fuel cycle can be obtained with a moderated neutron spectrum while a fast neutron spectrum is generally required to breed in the U-Pu cycle (Krepel, 2021). As far as poisoning resulting from fission products is concerned, it is worse in a thermal neutron spectrum than in a fast neutron spectrum, and the rate at which fuel reprocessing is performed can become a major issue. However, continuous extraction of the fission products is a possibility given the liquid nature of fuel in molten salt reactor (Mathieu et al., 2006; Ignatiev, 2021). This has been demonstrated in the conceptual design of the molten salt breeder reactor (as shown in Fig. 6) in the 1970s that aimed at investigating the feasibility of low-cost electricity production with a low specific inventory of fissile material, and simultaneously a reasonably high breeding gain in a molten salt reactor. According to this design, all of the gaseous fission products and most noble metal particles can be removed by a fuel salt off-gas purging system. Another chemical process was designed to continuously remove fission products and ^{233}Pa from the fuel salt, and the bred ^{233}U could be recovered in order to provide necessary amounts of fissile material (Delpech et al., 2009) (Fig. 7).

Although thorium fuel reprocessing has been carried out in water and organic solvents, it is more practical to employ pyroprocessing especially for the thorium fuel of molten salt reactor. One of the most obvious advantage is that the fuel used in reactor is essentially the same as that in pyroprocessing, which means no additional pre- or post- treatment of the fuel is required. In spite of this, this kind of thorium fuel reprocessing is not currently in significant use worldwide. The major reason is that reprocessing itself is not currently in favor, and places with this capability already have plants constructed that are based on separation in water and organic solvents. More advanced technology than the presently used fuels based on uranium and plutonium is therefore required. Another problem associated with thorium fuel processing is that many of the daughters of ^{232}Th and ^{233}U are strong gamma emitters (as shown in Fig. 8) which makes it difficult and dangerous to reprocess the used thorium fuel. For example, although ^{232}U itself is not particularly harmful, it quickly decays to the strong gamma emitter ^{208}Tl with significant quantities. The presence of ^{232}U and others significantly increases the requirements of shield and protection when processing thorium fuel, and this could increase the complexity for the development of pyroprocessing technology aiming at thorium fuel reprocessing (Morss et al., 2006). Finally, pyroprocessing separation technologies has not yet been demonstrated to achieve high separation rates, and their industrial implementation remains complex and there is currently no real industrial feedback. However, the separation rate issue is not likely a problem if pyroprocessing is used for the treatment of molten salt fuels since it is possible to partially drain the liquid fuels from the reactor which can be fed by new fuels after pyroprocessing later. This lowers the requirements for the separation rate as long as the drain-feed cycle is maintained at a level that assures the normal operation of the reactor. It might not be so advantageous to pyroprocess the fuels from other types of reactors due to the increased complexity for the front-end and back-end operations (dissolution, conversion et al.).

The key issues of the proliferation-concern

An increasing number of countries have taken nuclear energy as a preferred approach in response to the environment deterioration and energy supply deficit. The rapid expansion of nuclear technologies, however, would pose a great challenge to nuclear non-proliferation, especially for the Generation IV nuclear reactor systems (Stanculescu, 2021) which significantly differ from current nuclear fuel systems. As an alternative to U-Pu fuel cycle, Th-U fuel cycle has also drawn some attention although it is not yet commercially available. The decay path of thorium is well understood. Pure ^{232}Th forms ^{233}Th while bombarded with neutrons, which has a half-life of 22 min and β -decays to ^{233}Pa . ^{233}Pa has a half-life of 27 days and becomes ^{233}U through β -decays. Under IAEA Safeguards Agreements, pure ^{233}U is treated identically to plutonium (i.e. a significant quantity is defined as 8 kg and amounts over 2 kg are treated as Category I materials) (International Atomic Energy Agency, 2002, 2011). The suggested categorization presented in Table 2 defines ^{233}U denatured with ^{238}U to be an equivalent categorization to denatured ^{235}U (Ashley et al., 2012a). Thus, ^{233}U poses proliferation risks.

However, in Th-U fuel cycle, the presence of high energy gamma rays (2.6 MeV from ^{208}Tl) emitted by the daughter products of ^{232}U results in the robustness or physical protection of Th-U fuel cycle (Gangotra et al., 2014). Strong gamma rays not only cause great damage to operators and equipment, but also are difficult to be detected. They also put forward higher requirements for remote operation, which makes ^{232}U a vital measurement for thorium-based fuel cycle proliferation resistance assessment. Jungmin Kang et al. calculated the relationship between the radiation dose of ^{233}U and the ^{232}U content based on the reaction chains to produce ^{232}U (as shown in Fig. 9). High burn-up fuels (e.g. PWR fuel with a discharge burn-up of 70 GWd/t) is analyzed, the radiotoxicity of a 5 kg bare uranium metal, with an assumed ^{232}U component of 0.001% is 130 mSv/h at 0.5 m, after 1 year of decay time (Kang and Frank, 2001).

Mass, isotopic mix, heat and radiotoxicity of the nuclear materials, technical characteristics (detectability, technical level, nuclear facilities, etc.) and institutional arrangements of nuclear energy systems all have an impact on nuclear proliferation performance. For the front-end of the thorium-based fuel cycle, the type of fuel used to initiate the reactor is the main factor to be considered. Unlike uranium, there is no need for enrichment process for Th-U fuel cycle, which reduces the proliferation risks. In the operation stage, it is necessary to focus on the monitoring of gamma rays in the reactor, since the concentration of ^{232}U in the reactor will directly affect the difficulty of ^{233}U extraction, while ^{232}U production is related to the energy spectrum, fuel ratio and burnup of the reactor. The post-processing scheme also affects the technical difficulty of ^{233}U extraction, hence has an influence on the proliferation performance. After decommissioning, nuclear waste needs to be disposed. The fractions of different nuclear materials in

waste will affect the radiation quantity, heat release, spontaneous neutron generation rate, etc. The amount of spent fuel in Th-U fuel cycle is relatively small and stable, which does not react with water and is favorable for dry and wet storage.

Ashley et al. (Ashley et al., 2012b) conducted an extensive discussion on non-proliferation of Th-U fuel cycle in comparison to U-Pu fuel cycle, and raised several open questions that why the USA stopped pursuing ^{233}U for weapon purposes, how to define the weapon grade uranium vector when ^{232}U and ^{233}U are involved, whether Th-U fuel cycle systems would provide additional pathways to obtain sensitive nuclear materials, whether they are suitable to adopt the same U-Pu fuel cycle non-proliferation criterion (20% low-enriched uranium) and whether they are more difficult to be safeguarded. Although all these questions remain to be answered, some progress have been made in the related studies on Proliferation Resistance (PR) of Th-U fuel cycle, especially for MSR and CANDU since they are both considered most suitable for thorium utilization (Wang, 2016).

In addition, the accumulation of Pa is also one of the proliferation risks of Th-U fuel cycle. Pure ^{233}U can be produced by beta decay from ^{233}Pa , which makes the nuclear fuel cycle containing $^{233}\text{U}/\text{Pa}$ separation recycling process riskier compared to the once-through fuel cycle. It has been demonstrated that around 200 g of thorium metal could produce 1 g of ^{233}Pa and hence 1 g of ^{233}U . However, beta decay of 1 g ^{233}Pa produces 50 W of heat, and separation equipment is exposed to strong radioactivity, which complicates the handling.

Several proliferation assessment methodologies have been put forward world widely as shown in Table 3. In 2000, a PR assessment methodology dedicated for innovative nuclear reactors and fuel cycles was proposed by the International Project on

Innovative Nuclear Reactors and Fuel Cycles (INPRO) which had been launched by IAEA (IAEA, 2003). And the PR&PP framework proposed by GIF (Generation IV International Forum), which divided proliferation risk into national proliferation and threats from terrorisms (Nishimura et al., 2004). A toolbox containing the potential theories of expert elicitation, Multi-attribute Utility (MAU) theory, fuzzy sets and possibility theory, analytic hierarchy procedure, dynamic modeling, two-sided methods and logic diagrams was offered, and some of the models and/or methods in this toolbox were also extensively developed in the later related studies (Charlton et al., 2007). Nevertheless, these methods have some limitations in the assessment of Th-U fuel cycle, and it should be effectively addressed in the future safeguard analysis or design.

Thorium fuel cycles face unique proliferation resistance problems compared with U-Pu fuel cycles as introduced above. And these problems depend very much upon how thorium fuel cycles are implemented. Some measures, including raising ^{232}U content by increasing discharged burnup and/or by denaturing ^{233}U with ^{238}U , were put forward to effectively enhance the proliferation performance (Vanderhaegen and Janssens-Maenhout, 2010).

Comparison of the waste characteristics of the U-Pu and Th-U fuel cycles

The nuclear wastes in the fuel cycle mainly consist of fission products and actinides. In the following, the differences of the waste characteristics between the U-Pu and Th-U fuel cycles are detailed.

1) Fission products

For a given amount of thermal energy produced in a reactor core, the amount of fission products is essentially the same in thorium or uranium fuels because a fission reaction releases about 200 MeV, regardless of the fission nuclide, and gives birth to two fission products. The relative proportion of each of the radioisotopes is slightly different according to the origin of the fission (^{235}U , ^{239}Pu , ^{241}Pu , ^{233}U) and consequently the evolution of the total radiotoxic inventory of these fission products is slightly different between the two cycles. However, as most of the radioactivity from fission products disappears after a few centuries, and there is little difference in the amounts of long-lived mobile fission products that tend to drive repository safety cases. Therefore, there is almost no difference between the U-Pu and Th-U fuel cycles with regard to the fission products (OECD-NEA, 2015a). The fission products account for about 3% of the total mass of the spent fuel, which are considered as radioactive waste or may be separated further for various industrial and medical applications. As shown in Fig. 10, the fission products include every element from zinc through to the lanthanides. Much of the fission yield is concentrated in two peaks: one in the second transition row (Zr, Mo, Tc, Ru, Rh, Pd, Ag) and the other later in the periodic table (I, Xe, Cs, Ba, La, Ce, Nd). Most of the fission products are either non-radioactive or only short-lived radioisotopes. But a considerable number of fission products are medium to long-lived radioisotopes such as ^{90}Sr , ^{137}Cs , ^{99}Tc and ^{129}I (Encyclopedia, n.d.-b). The yield ratios of long-lived fission products (LLFP) for thermal neutron fission of ^{233}U , ^{235}U and ^{239}Pu are listed in Table 4. Large differences can be observed for some LLFPs, especially for ^{129}I which is a mobile long-lived fission product and significantly contributes to the final impact of the repository in reducing environment. The yield ratio of ^{129}I in ^{233}U fission is about triple that in ^{235}U fission, implying larger impact would be imposed by Th-U fuel cycle on disposing high level nuclear wastes from the view of LLFPs.

Fig. 10 Fission product yields by mass for thermal neutron fission of U-235, Pu-239, a combination of the two typical of current nuclear power reactors, and U-233 used in the thorium cycle (Encyclopedia, n.d.-a). From Encyclopedia, <https://encyclopedia.thefreedictionary.com/Fission+product+yield>.

Table 4 Yield ratio of long-lived fission products for thermal neutron fission of ^{233}U , ^{235}U and ^{239}Pu .

Nuclide	Half-life (Ma)	Yield- ^{233}U	Yield- ^{235}U	Yield- ^{239}Pu
^{99}Tc	0.211	9.2324E-02	1.1484E-01	1.1678E-01
^{126}Sn	0.230	2.2433E-03	5.6143E-04	1.9861E-03
^{79}Se	0.327	2.8676E-03	8.9447E-04	4.3452E-04
^{93}Zr	1.53	6.9788E-02	6.3463E-02	3.7975E-02
^{135}Cs	2.3	6.2680E-02	6.5392E-02	7.6209E-02
^{107}Pd	6.5	1.1453E-03	1.4619E-03	1.2700E-07
^{129}I	15.7	1.5913E-02	5.4335E-03	1.3714E-02

2) Actinides

The difference between the U-Pu and Th-U fuel cycles may come from the amount of depleted uranium and minor actinides generated in the two cycles.

In the U-Pu fuel cycle, 96% of the mass of spent fuel is the remaining uranium: most ^{238}U and a little ^{235}U . In general, ^{235}U would be less than 0.83%. In addition, the remaining uranium will contain ^{236}U with 0.4%, which is not found in nature and can be used as a fingerprint for spent reactor fuel. About 1% of the mass is ^{239}Pu and ^{240}Pu resulting from ^{238}U conversion, which may be considered either as a useful byproduct, or as dangerous and inconvenient waste (Encyclopedia, n.d.-b). One of the main concerns regarding nuclear proliferation is to prevent this plutonium from being used by states to produce nuclear weapons. If the reactor has been used normally, the plutonium is considered as reactor-grade. The plutonium contains more than 19% ^{240}Pu and less than 80% ^{239}Pu , which makes it not ideal for making nuclear weapons. If the irradiation period is short, the plutonium is considered as weapons-grade (more than 80%, up to 93%). In the U-Pu cycle, significant amounts of three long-lived transuranic elements (other than plutonium) are generated (as shown in Fig. 11): ^{237}Np (with half-life of 2.14 million years), americium (mainly ^{241}Am , with a half-life of 432 years and ^{243}Am , with a half-life of 7380 years) and curium (mainly ^{245}Cm , with a half-life of 8530 years). These nuclides are particularly radiotoxic alpha emitters and the main contributors to the total radiotoxic inventory of final radioactive waste after a few hundred years (with the exception of plutonium, which may be recycled depending on the specific fuel cycle). These nuclides have low solubility limits in water and have very low mobility in geological media, which practically excludes the possibility of their migrating to the biosphere, at least over timescales during which they could deliver significant radiological doses to living species. The partitioning of these elements and their subsequent transmutation in reactors is an option that has been studied nowadays to further minimize this risk. Research has been conducted in this direction for many years in various countries (such as France, Japan and the United States) suggesting that these operations could be carried out industrially. However, this would require the implementation of complex processes and technologies with specific additional costs.

In the pure Th-U fuel cycle, almost none of the above mentioned minor actinides (Np, Am, Cm) are produced because five captures in ^{232}Th are generally necessary to produce transuranics, as displayed in Fig. 11. Americium and curium mainly come from plutonium (via neutron capture and various radioactive decays), while ^{237}Np mainly comes from ^{235}U (via producing ^{237}U and decays to ^{237}Np). In the Th-U fuel with a burn-up of ~ 60 GWd/t, there is about 30 times less ^{237}Np , than in the U-Pu fuel cycle. This ratio is about 60 for ^{238}Pu (with half-life of 88 years) (Lung, 1997). However, the spent nuclear fuel in the Th-U fuel cycle will have U-233, with a half-life of 159,200 years. This will affect the long-term radioactive decay of the spent fuel. When compared with MOX fuel, the activity around one million years in the Th-U cycle will be higher due to the presence of

the not completely decayed U-233. Irradiation of thorium fuel also increases the accumulation of specific long-lived heavy radionuclides, some of which have a much higher radiotoxicity than their counterparts in the U-Pu fuel cycle. The most prominent are (OECD-NEA, 2015b):

- a) ^{233}U with a half-life of 159,200 years. ^{233}U has a daughter product of ^{229}Th , which contributes significantly to the radiotoxicity of the spent fuel. However, this difference becomes much less noticeable if ^{233}U is recycled and ^{233}U is usually necessary to be reused as it is an attractive fissile fuel.
- b) ^{231}Pa with a half-life of 33,000 years, which results from the beta decay of ^{231}Th (with a half-life of about 25 h) which in turn is formed by (n, 2n) reactions of ^{232}Th . The long half-life of ^{231}Pa makes it an important contributor to long-term global radiotoxic inventory. It has a particularly high radiotoxicity, even higher than the principal plutonium isotopes (^{239}Pu and ^{240}Pu).
- c) ^{232}U with a half-life of 70 years. The main burden comes from its decay products (^{212}Bi and ^{208}Tl), which are highly radiotoxic (with gamma-ray radiation of 1.6 and 2.6 MeV) and which would result in heavy shielding requirements in recycling plants.

In conclusion, in terms of the potential reduction of the radiotoxic mass of the nuclear waste compared to the U-Pu fuel cycle, the benefits of a closed Th-U fuel cycle at equilibrium are more modest. One disadvantage of the Th-U fuel cycle arising from reprocessing spent fuel (for recovery and recycle of ^{233}U), is that it is the required to avoid off-gas radon transport of the highly radioactive radon daughters through high-efficiency particulate air filters to the environment. Therefore, retention of about 10 min of the off-gas must be incorporated into the off-gas system design to allow for ^{220}Rn decay before high-efficiency particulate air filtration (OECD-NEA, 2015a, b).

Glossary

GHG Green-house gases gas that absorbs and emits radiant energy within the thermal infrared range, causing the greenhouse effect. The primary greenhouse gases in Earth's atmosphere are water vapor (H₂O), carbon dioxide (CO₂), methane (CH₄), nitrous oxide (N₂O), and ozone (O₃). They are classically expressed in CO₂ equivalent or CO₂ equivalent.

HLW High-level waste corresponds to the most radiotoxic nuclear waste containing long-lived radionuclides and high radiation fields. They corresponds either to nuclear glasses containing the fission productions, or spent nuclear fuel.

ILW-LL Long-lived intermediate level waste corresponds to intermediate level nuclear waste containing long-lived radionuclides. It basically consists of materials contaminated by actinides in the fuel cycle, in particular the remaining pieces of fuel cladding and hulls and end-pieces.

Life cycle assessment (or LCA) Methodology for assessing environmental impacts associated with all the stages of the life-cycle of a commercial product, process, or service. Environmental impacts are assessed from raw material extraction and processing (cradle), through the product's manufacture, distribution and use, to the recycling or final disposal of the materials composing it (grave).

LLW-LL or SL Long-lived or short-lived low level waste corresponds to waste containing (or not) radionuclides with half-life below 30 years at a low concentration. They mainly comes from the operation of industrial or research facilities and are currently conditioned in drums encased in concrete cells which will finally be protected by additional grounds.

VLW Very low level waste contains a very low radionuclides content, potentially none, but has to be specifically managed due to the absence in France of liberation threshold below which are cleared from any contamination. They are stored in an existing industrial shallow deposit in France.

Introduction

The increasing impact of the overall environmental crisis leads public opinion and stake-holders to take into deeper consideration the actual environmental footprint of the different industrial activities. It not only aims at quantifying green-house gases emissions which contribute to the global climate change, but also other indicators contributing for instance to biodiversity preservation, pollution prevention, resource saving ... Nuclear energy which has always been controversial is hence also questioned on its actual relative impact by comparison to other energy sources, in particular renewables energies. For many opponents, back-end of the fuel cycle is considered as the most controversial part of the nuclear energy system:

- (i) recycling deals with plutonium which is considered by some opponents as the most dangerous radioactive element, and is linked to military applications in people's mind;
- (ii) recycling also requires treating highly radioactive spent nuclear fuel, which they assume to be very polluting;
- (iii) geological repository aims at confining nuclear waste, the lifetime of which is well beyond the human history.

Although it is not scientifically sound, fuel cycle back-end is considered by many opponents as very polluting activities, which should justify the nuclear energy phasing out. Developing reliable and scientifically based environmental indicators is hence of

prime importance not only to have a reliable assessment of the environmental footprint of nuclear energy by comparison to other energies, but also to have a reliable picture of the respective contribution of the various nuclear fuel cycles part.

Numerous sustainability indicators have been developed and proposed by economics or system ecologists to rank given systems by comparing one to each other in terms of sustainability (see for example Gasparatos et al. (2008), Buchholz et al. (2009), Gallego-Carrera and Mack (2010), Evans et al. (2010)). However, many indicators are not yet internationally agreed upon and are for some of them not easily and objectively quantifiable, for instance in the societal field (Evans et al., 2009; Lior, 2010; Piera, 2010). Furthermore, beyond the individual and elementary indicators, there is a real need for composite indicators, named indices, which can be more easily handled by the stakeholders. However, deriving indices is also a matter of real debate on the way to aggregate numerous and heterogeneous criteria in a limited number of upper-level indices (Gasparatos et al., 2008).

Life cycle assessment (or life cycle analysis, LCA) is the main basis for deriving relevant and integrated indicators and has been widely applied to different energy sources, such as wind power, hydroelectricity, biomass, photovoltaic energies (Dones et al., 2009; Lior, 2010; Goralczyk, 2003; Evans et al., 2009; La Rovere et al., 2010). Several studies have also addressed the specific case of a target system (for instance a major city) and attempted to rank the different types of energy sources in order to derive the most “sustainable” one (Jovanovic et al., 2010; Schwenk-Ferrero and Andrianov, 2017). However, very few studies have dealt with the specific case of nuclear energy, and they yield a wide range of results, depending on the chosen nuclear fuel cycle scenario, the type of technology implemented (especially for the uranium enrichment) and the national electrical mix (e.g., Kessler (2002), Lenzen (2008) and Dones et al. (2009)).

Rationale and limitations of LCA

Several methodologies have been described to implement relevant LCA. Among the different approaches and studies, the most critical point concerns the database to be used for the reference primary data. Most of the studies are directly using the well-known Ecoinvent database, which has been developed by several institutions associated to the ETH Zürich (see the webpage <https://www.ecoinvent.org/>). However, some of the data may not be of relevance or are obsolete, in particular for nuclear activities, as very few studies are targeting to update them. For instance, the enrichment process is still considered to be based on gaseous diffusion which is quite obsolete and less and less used. For instance, in France, gaseous diffusion plant (called GB-I plant) was closed in 2012 and replaced by a more modern plant based on ultra-centrifugation which consumes 24 times less electricity (100 kWh/UTS instead of 2400 kWh/UTS). As the enrichment process requires large amount of electricity to be operated, its overall impact strongly depends on the carbon intensity of the country where the process is implemented. Enriching uranium in a country where electricity has a low carbon content as in France yields much lower CO₂ emissions than implementing it in country where electricity has a high carbon content such as China. Extrapolation from one country to the other is therefore all but obvious and requires a lot of precaution. Subsequently, direct use of Ecoinvent database may lead to very significant bias in the overall result, in particular if a careful check of the basic supporting data is not realized. For this reason, results of LCA can be highly scattered from one study to the other, yielding difficulty to get a representative trend without a more in-depth analysis. For instance, CO₂ emissions for nuclear electricity can vary in the literature by almost two orders of magnitude, between a few gCO₂/kWh to more than 100 gCO₂/kWh for the most extreme ones (Lenzen, 2008; Warner and Heath, 2012; Turconi et al., 2013).

In order to overcome this intrinsic difficulty, Poinssot and coworkers developed in a previous study a specific database solely based on factual and published data concerning the actual impact of the nuclear fuel cycle in France (Poinssot et al., 2014; Serp et al., 2017; ASN, 2019). This study was developed by using the Process Chain Analysis (PCA) approach from cradle to grave (construction, operation, dismantling, including transports between all the fuel cycle facilities). The analysis was performed on a yearly basis for the whole French nuclear fuel cycle. For all the facilities (fuel cycle plants or reactors), both the contribution of their construction and dismantling, and that coming from their operation along their lifetime was considered with a lifetime assumed to be 40 years, which is likely a conservative assumption for most of them. In order to simplify the calculations, it was assumed that the French reactors park is only fed by the fuel from Orano (at that time, Areva) front-end plants, which is actually only true for about 50% of the annual fuel input. Finally, input data were directly taken from the actual consumption and release data for year 2010 as described in the yearly environmental and safety report produced by any nuclear facility in France thanks to the Nuclear Safety and Transparency Law of 2006.

This study was therefore a unique opportunity to derive relevant estimate of the contribution of the different fuel cycle steps on the overall environmental footprint, which explains why it is taken as a relevant and reliable case study in this article.

Description of the nuclear fuel cycle

The simulation is based on the French nuclear fuel cycle taken as a representative situation. It considers the whole fuel cycle, from the ore mining to the geological disposal, through the conversion, the enrichment, the fuel fabrication, the electricity production within the reactors, the fuel storage, the fuel recycling and the different types of waste conditioning plant and interim storages. Geological Disposal for ultimate waste planned to be built in France by 2025 is also included. Non-reprocessed spent fuels are

Fig. 1 French reference fuel cycle and its representative streams (Year 2010). From Poinssot Ch, Bourg S, Ouvrier N, Combernoux N, Rostaing C, Vargas-Gonzalez M and Bruno J. (2014) Assessment of the environmental footprint of nuclear energy systems. Comparison between closed and open fuel cycles. *Energy* 69: 199–211.

not considered as waste since they are planned to undergo a delayed recycling for feeding future 4th generation Fast Neutron Reactors FNR (for instance Sodium Fast Reactors (SFR)) (Fig. 1).

Eight key generic environmental indicators have been selected based on their technical relevance and frequency in literature:

- GHG emissions (mass of CO₂ equivalent, g per electrical kWh).
- the atmospheric pollution (mass of SO_x and NO_x, mg per electrical kWh).
- the water pollution (mass of pollutants, mg per electrical kWh).
- the land-use (surface area, m² per electrical GWh).
- the water consumption (water is not released to the environment) and withdrawal (water is released after cooling) (volume of water, L per electrical kWh).
- the production of technological waste (mass of waste, g per electrical MWh).

Three additional indicators were also selected to address the radioactive gaseous and liquid releases (activity, Bq per electrical kWh) and the solid radioactive waste production (mass or volume of waste, g per electrical MWh, or m³ per electrical MWh).

Finally, five potential impact indicators have also been assessed: soil acidification, surface waters eutrophication due to phosphate release, photochemical ozone creation potential (POCP) in the lower atmosphere, overall eco-toxicity and human-toxicity. By definition, they refer to a potential maximum impact that the overall liquid and gaseous release from all the fuel cycles plants could generate and represent boundary overestimation of the environmental impact (Fig. 2).

Comparison of the nuclear energy environmental footprint with other energy sources

Based on this approach, the LCA of the entire French nuclear fuel cycle was performed, where every activity, from the mining uranium extraction down to the spent nuclear treatment and recycling, and the ultimate waste geological disposal were considered. Even with such a comprehensive description of this industry, the overall environmental footprint of the French nuclear energy is very low by comparison to other energy sources as shown in this Fig. 3.

Nuclear energy is within the top-3 of the most environmental-friendly energy sources, in the same range as hydropower and windpower for most of the indicators except the water withdrawal and the technological waste production. For some of them as GHG emissions, nuclear energy is even the most environmental friendly energy source, far from what people have often in mind and about two to three times lower than the common value proposed by EcoInvent (12 g CO₂ equivalent/kWh).

Fig. 2 Key indicators described in this article. From Poinssot Ch, Bourg S and Boullis B (2016) Improving the nuclear energy sustainability by decreasing its environmental footprint. Guidelines from life cycle assessment simulations. *Progress in Nuclear Energy* 92: 234–241.

Fig. 3 Comparison of the relative environmental impact of the different energy sources normalized to the nuclear energy impact for the selected impact indicators. Values higher than unity indicate that the impact is higher than that of nuclear energy. Values lower than unity indicate that the impact is lower than that of nuclear energy. Adapted from Poinssot Ch, Bourg S, Ouvrier N, Combernoux N, Rostaing C, Vargas-Gonzalez M and Bruno J (2014) Assessment of the environmental footprint of nuclear energy systems. Comparison between closed and open fuel cycles. *Energy* 69: 199–211.

Place of nuclear fuel cycle within the overall nuclear environmental footprint

Based on the LCA approach and the previous assumptions, the relative contributions of each step of the nuclear fuel cycle has quantitatively been assessed by associating the construction/deconstruction impact of each plant to their respective cycle step (Fig. 4).

This figure clearly illustrates the relatively low impact of the fuel cycle back-end by comparison to the front-end or reactors activities: Fuel cycle back-end activities are all below 10% of the overall environmental impact, except for CO₂ emissions that represent 30%. For water withdrawal or consumption, ecotoxicity, human toxicity, fuel cycle back-end contributions are even negligible and below 1% of the overall impact. Within the back-end activities, geological repository and reprocessing are the most significant contributions depending on the indicators: repository dominates the GHG emissions, the landuse, the NO_x emissions and the waste production, whereas reprocessing dominates the SO_x emission, water pollution and eutrophication.

Fig. 4 Relative contribution of each step of the fuel cycle to the environmental and technological impact indicators for the French fuel cycle. From Poinssot Ch, Bourg S, Ouvrier N, Combernoux N, Rostaing C, Vargas-Gonzalez M and Bruno J (2014) Assessment of the environmental footprint of nuclear energy systems. Comparison between closed and open fuel cycles. *Energy* 69: 199–211.

Reversely, fuel cycle front-end plays a major role on the overall impact, with the exception of the water consumption/withdrawal and the technological waste production, usually representing between 50% and >99% of the overall impact. It clearly illustrates the very strong disequilibrium existing between front-end and back-end activities, this latter being far more environmental-friendly than the front-end despite the usual thinking. This strong imbalance supports any option that would allow either reducing the environmental impact of the front-end activities, or decreasing the volume of uranium to be treated within the front-end activities, in particular by implementing an efficient recycling of the spent nuclear fuels.

Impact of mono-recycling in PWR

In order to better assess the relative impact of recycling on the overall environmental footprint of nuclear energy systems, the impact of a theoretical energy system producing the same amount of electricity but without any recycling was estimated by correcting adequately the various material fluxes in the nuclear fuel cycle. Basically, an additional uranium flux in the front-end was to be included to compensate the energy produced by uranium and plutonium recycling. The corresponding overall fuel cycle is given in Fig. 5.

Fig. 5 Description of a theoretical nuclear fuel cycles producing the same amount of electricity without any spent nuclear fuel recycling. The uranium flux in the front-end has therefore to be increased by roughly 1500 t/year (Poinssot et al., 2014). From Poinssot Ch, Bourg S, Ouvrier N, Combernoux N, Rostaing C, Vargas-Gonzalez M and Bruno J (2014) Assessment of the environmental footprint of nuclear energy systems. Comparison between closed and open fuel cycles. *Energy* 69: 199–211.

Comparison of the indicators for the two fuel cycles allowed us to directly assess the impact of the recycling. It clearly demonstrates that recycling has a very positive impact on the overall environmental footprint of the nuclear energy, with the exceptions of rare gases and tritium emissions, and ILW-LL waste.

For a fuel cycle where up to 20% of natural uranium can be saved thanks to U and Pu recycling, the improvement of the environmental footprint ranges between 10% and 20% of the initial open (once-through) fuel cycle footprint (Fig. 6).

Regarding the High-Level Waste which concentrates more than 99% of the initial radioactivity, the gain is much more substantial as it is decreased by a factor of more than two due to the efficient conditioning of the ultimate waste as nuclear glass. Reversely, the spent nuclear fuel processing creates new waste which are contaminated by long-lived radionuclides and are therefore categorized as ILW-LL, in particular CSNF hulls and end-pieces (Fig. 7).

It is also noteworthy that recycling allows a significant reduction of the HLW burden as both the residual thermal power, the residual radioactivity and the volume of waste are significantly decreased by CSNF recycling. Therefore, it has a very positive impact on the geological repository design as the residual heat power is one of the most influencing parameters for establishing the repository volume and surface (Fig. 8).

Finally, although releases of tritium and noble gases into the atmosphere and ocean are increased by recycling activities, their impact has been demonstrated to be well below the health regulation (in the order of 17 $\mu\text{Sv}/\text{year}$ for the surrounding fishermen, and 24 $\mu\text{Sv}/\text{year}$ for the surrounding farmers, to be compared to the average French natural radioactivity of 2400 $\mu\text{Sv}/\text{year}$) and with no impact on the health of the surrounding population (Fig. 9).

As a conclusion, CSNF recycling as an overall positive impact on the environmental footprint of the whole nuclear energy system due to the dominant impact of the front-end activities which are reduced when recycling is implemented.

Impact of multi-recycling in FNR

Similar study was performed to assess the potential impact of implementing CSNF multi-recycling thanks to the use of Generation IV Fast Neutron Reactors (FNR) as Sodium fast reactors. In order to overcome the lack of actual impact data for the Generation IV reactors, past French industrial experience with FNR was used and data from Phenix and Superphenix reactors operation were considered (Serp et al., 2017).

Fig. 6 Relative evolution of the environmental indicators when simulating the implementation of the mono-recycling within the French nuclear fuel cycle. Negative values indicate that the impact is lower with recycling, whereas positive value indicate that the impact is lower without recycling. Comparison between closed and open fuel cycles. *Energy* 69: 199–211.

Fig. 8 Impact of CSNF recycling on the repository surface area and volume. Adapted from Poinssot Ch, Bourg S, Ouvrier N, Combernoux N, Rostaing C, Vargas-Gonzalez M and Bruno J (2014) Assessment of the environmental footprint of nuclear energy systems. Comparison between closed and open fuel cycles. *Energy* 69: 199–211.

In such a fuel cycle, since France has stockpiled more than 300,000 Mt. of depleted uranium, the mining activity would not be necessary anymore, the multirecycling of the plutonium provides the fissile material and the depleted uranium the fertile material (Fig. 10).

It yields to similar conclusions than before, i.e., the more intensive the recycling, the lower the environmental impact as evidenced by the following synthetic figure (Fig. 11).

Fig. 9 Impact of CSNF recycling on gaseous and sea release in the back-end related to the impact of the reprocessing plant. RN stands for Radionuclides. Evidence of the beneficial effect of extensive recycling. *Energies* 10: 1445.

Conclusion

LCA approaches are relevant and powerful to assess the respective environmental footprint of any human activities as they allow us to consider the integrated contribution all along the activity lifetime, from cradle to grave. Based on this objective approach, environmental footprint of fuel cycle back-end was assessed by considering France as a reference case. It comes out that most of the environmental footprint of nuclear activities is due to the front-end activities rather than the back-end, the impact of which remains rather low. Within the back-end, geological repository and reprocessing are the most contributing activities, depending on the environmental indicators considered. This significant imbalance between front-end and back-end activities strongly support the environmental interest of implementing spent fuel recycling as it increases the back-end activities at the expenses of the front-end activities. Tentative simulations of future fuel cycles where multi-recycling could be implemented thanks to fast neutron reactors enlightens the very positive impact of recycling and the subsequent significant improvement of the environmental footprint since the accumulation of the depleted uranium stockpiled within the PWR operation lifetime would lead to a significant reduction of the uranium mining activity, not to say its full removal (Poinssot et al., 2016). Similar results have been obtained in other recent studies, especially from Schwenk-Ferrero and Andrianov (2017) where they compared different fuel cycle scenarios both on environmental footprint, waste management and economics. Unsurprisingly, nuclear fuel cycles with higher degree of recycling yields significantly improved environmental footprint. In contradiction to the common perception, the nuclear fuel cycle backend has a very little detrimental environmental impact and significantly contributes to improving the overall nuclear energy low environmental footprint by comparison to other energy sources.

Introduction and framework

High-level radioactive waste (HLW) and spent nuclear fuel (SNF) are inevitable by-products of nuclear-weapons manufacturing and nuclear-electricity generation. Reliable information about how much HLW and SNF have so far been created worldwide is hard to obtain. But, as an indication of the scale, approximately 90,000 metric tons of commercial SNF has been generated in the United States alone (GAO, 2019). Yet, despite efforts that began more than a half-century ago, none of the world's HLW and SNF has been permanently managed; all of it rests in temporary storage at hundreds of sites across the globe. The critical challenge of nuclear waste management today, then, is to identify both geologically sound and publicly supported locations where this material can be securely isolated for hundreds of millennia. (Similar challenges face efforts to construct a disposal facility for low- and intermediate-radioactive waste and uranium mill tailings. The development of a facility to dispose of low- and intermediate-level radioactive waste in Ontario is a typical example. This chapter, however, exclusively reviews work to dispose of HLW and SNF.)

The task of siting such an isolation facility, called here by convention a repository, can be conceptually understood as an iterative process: many potential sites “pass” through both “technical suitability” and “social acceptability” filters to yield fewer candidate sites. In concrete terms, the technical suitability filter specifies how factors affecting repository performance will be measured and the standards that performance must meet. The social acceptability filter refers to a range of governance processes, plebiscites, formal rules and regulations, and *ad hoc* public actions, such as demonstrations and protests. If all goes well, one of them is developed into a repository. A snapshot of that process is illustrated in Fig. 1. (This conceptualization was slightly modified and later was published in a report the author drafted for the U.S. Nuclear Waste Technical Review Board (NWTB, 2015). The reader is encouraged to consult that volume for a much more comprehensive analysis than space here permits.)

Significantly, the *order* in which potential sites proceed through the two filters depends on national laws, regulations, and practices. In some countries, the implementer passes potential sites first through the technical suitability filter and then the social acceptability one. In others, the process is reversed. But in all nations, *both* filters must be satisfied before a repository site can be successfully developed.

Early on, waste management programs focused almost exclusively on establishing the scientific and engineering foundations for evaluating whether a potential repository site was technically suitable. Implicitly—and sometimes explicitly—the presumption was that only specialist communities working for the implementer needed to be persuaded about the facility's performance. (For instance, it was not until 1975 in the United States that the implementer had to make its performance arguments to an independent regulator. In other nations, such as Germany, this separation was not required until well into the 21st century.) More recently, that presumption has come under strong attack. As a report prepared by the International Atomic Energy Agency (IAEA) emphasized:

Members of the general public and representatives of local communities recognize that they have a clear stake in the outcomes of [siting] decisions and almost always seek to have their views taken into account by the policy elites (IAEA, 2007).

Not surprisingly then, in many nations, interested and affected elements of the public demanded that the social acceptability filter be substantially raised in importance, even to the point that its requirements had to be met *before* the process could move

Fig. 1 Siting a Repository. Metlay D (2011) International Experience Developing Deep-Mined Geologic Repositories. *Presentation at AtomEco-2011, Moscow.*

forward. Thus, the history of nuclear waste management in countries with strong pluralist and democratic traditions is truly the history of how the order and the prominence of the filters intrinsic to the siting process were contested. (The author is not unaware of the possibility that the two filters may depend on each other or be influenced by a common third factor. For example, attitudes about whether nuclear power is a valuable energy option may influence views about both technical suitability and social acceptability. Space limitations prevent a discussion of this important question here. The interested reader should refer to (NWTRB, 2015) where it is considered in depth.)

This article explores that history by reviewing how waste-management programs in nine nations—Canada, Finland, France, Germany, Great Britain, Japan, Sweden, Switzerland, and the United States—evolved over the last half century. Although there is some value in telling each country's story separately, such an approach makes it harder to draw comparisons about why some countries appear to be on the brink of successfully developing a repository and why others are still struggling. As importantly, organizing the discussion by examining each nation sequentially masks the observation that each national program (with one exception, Finland) has followed essentially the *same trajectory*.

Thus section **"A strategy for long-term management of HLW and SNF emerges"** discusses how nations initially adopted a strategy that focuses almost exclusively on the technical suitability filter. Section **"Challenging the strategy: Social acceptability emerges as a critical concern"** describes how that strategy was criticized because it failed to give proper consideration to the social acceptability filter. Section **"Why is social acceptability so problematic?"** analyses the underlying bases for that criticism. Section **"Reconstructing the deep-disposal strategy"** considers how the strategy was reconstructed to elevate the importance of the social acceptability filter. Finally, section **"What have we learned? What does the future hold?"** assesses how national experiences inform us about securing social acceptability and what might be expected going forward.

A strategy for long-term management of HLW and SNF emerges

During the first decade of the nuclear age, the HLW from weapons-material production was stored in tanks. The design of the first commercial reprocessing plant at West Valley, New York, adopted the same approach. For the reprocessing plants at Sellafield in Britain and La Hague in France tank storage of HLW was also adopted. For many involved in those efforts, however, the technical and organizational requirements for perpetual care seemed mismatched with the longevity of the wastes' hazards. Could institutions be counted on to secure the material over millennium? Perhaps a less risky method could be found.

It is hard to overestimate the impact of a report prepared under the aegis of the US Academy of Sciences (NAS, 1957). A specially appointed panel proposed burying the material in a conventionally mined repository deep underground. (The panel envisioned disposing of liquid HLW. At the time, leaders of the nuclear power industry expected that commercial SNF like weapons-production SNF would also be reprocessed to extract fissionable plutonium and uranium. The requirement that liquid HLW had to be solidified was not established until 1970 (AEC, 1970). Several years later, a technical consensus emerged that SNF could be just as well disposed of in a repository.) In particular, the NAS report observed that salt formations might prove to be an appropriate host-rock type because of its plasticity and isolation from flowing water.

After a period during which the radioactive waste disposal issue was largely ignored by policymakers, the panel's general strategy gained traction in many nations where HLW and SNF had already been or were about to be created. In the United States, a federal repository was mandated in 1970 (AEC, 1970). After comparing a variety of strategies, the Department of Energy (DOE) formalized the strategy of deep-mined, geologic disposal ten years later (DOE, 1980). Based on an extensive review, the Swedish Government initially approved the deep-disposal strategy (KBS-1 for HLW now replaced by KBS-3 for SNF) in 1979 (Elam and Sundqvist, 2011).

In other nations, disposal in a deep-mined, geologic repository became the default strategy that was not closely scrutinized and evaluated beforehand. For example, in 1965, field investigations began in Germany (BMW, 2008). In 1978, the Swiss nuclear waste legislation set forth requirements for siting a repository (Vomvoris et al., 2013). The French waste-management implementer started its repository research in 1982 (ANDRA, 2019).

It would take many years of dedicated and creative research to fill in the technical details of the strategy advanced by the NAS panel. But based on those studies, a consensus emerged within the scientific and engineering communities that HLW and SNF could be safely disposed not only in salt, but also in clay, crystalline rock, and volcanic formations. (See the chapters in this volume for additional details about the safety cases associated with each of those host rocks.)

What all these nascent national programs had in common was the belief that implementing the strategy involved a relatively simple, straightforward scientific and engineering task—a technical fix (Metlay, 1978). Nowhere in the document authored by the NAS panel, for instance, does it suggest or even imply that affected communities might raise objections or, more generally, that the how and where of disposal represented a broad societal decision. (In fairness, it must be noted that, through the last decades of the 20th century, the panel's perspective was entirely consistent with prevailing practices governing how large-scale technologies were implemented. Small groups of scientists, engineers, industrial leaders, and government officials exercised decisive decision-making power.) By the end of the 1970s and certainly by the end of the 1980s, it was clear that this strategy, which focused narrowly on the technical suitability filter and which hardly recognized the significance of the social acceptability one, would face substantial challenges and doubts on those accounts.

Challenging the strategy: Social acceptability emerges as a critical concern

The Germans were the first to discover the on-the-ground reality of that observation. In 1966, a year after field studies had gotten under way to explore salt formations at Krummendeich and Bunde, the studies had to be terminated because of public opposition (BMW, 2008). In 1976, the State of Lower Saxony began an extensive evaluation of 140 potential locations where the deep-disposal strategy might be executed. This assessment culminated in the selection of a site near the town of Gorleben, which lay adjacent to the East German border. Over the next 40 years, that decision became enmeshed in intense technical and political controversies (Tigemann, 2019). As a result, the social acceptability of the site was never established.

In the United States, the Atomic Energy Commission (AEC) focused its efforts to implement the deep-disposal strategy in a salt formation near Lyons, Kansas during the late 1960s (De la Bruheze, 1992). Technical problems with the site led state officials to successfully campaign against its selection for a repository. Subsequently, governors of Michigan and New York maintained that the federal strategy was socially unacceptable and blocked DOE from conducting surface-based investigations in those states (Carter, 1987). In response, Congress in 1982 passed the Nuclear Waste Policy Act that mandated a site-selection process that ostensibly relied solely on technical considerations. It allowed the *situs* state to disapprove of its selection subject to an override by both houses of Congress. It also expanded the opportunities for interested and affected parties to participate in the process but gave them little formal power to influence its outcomes.

Nonetheless, potentially affected states soon thereafter launched intense campaigns, arguing that the sites DOE had finally settled upon were unacceptable. Five years later, this strong public opposition prompted Congress to amend the 1982 law to exclude all locations except Yucca Mountain in Nevada (Walker, 2009). (The exploding cost of characterizing (investigating) multiple sites was the rationale for exploring a single site. The politics of the process explains why Yucca Mountain was chosen: Nevada's congressional delegation was powerless in the face of strong opposition from Washington and Texas, the two other states then under consideration (Colglazier and Langum, 1988).) Notwithstanding the fact that Congress in 2002 specifically approved the site's selection and that the Nuclear Regulatory Commission's (NRC) staff in 2014 positively reviewed the application to construct a repository, the State of Nevada continues to object.

In 1978, the Swiss implementer, Nagra, started to look at potential repository sites in granite formations. A decade later, the Swiss Government concluded that attempts to execute the deep-disposal strategy in crystalline rock were not likely to be successful (Nagra, 2002). It encouraged Nagra to shift its focus to the Opalinus clay formations that lay in the northern part of the country. Nagra first advanced a proposal to construct a repository for long-lived, intermediate-level waste in the town of Wellenberg located in the Canton of Nidwalden. In 1993, despite support from the community's leaders, nearly 52% of the public voted against the proposal in a cantonal referendum.

In response to this setback, the federal government appointed an independent advisory committee, which recommended monitored long-term geologic disposal and the continuation of the work at Wellenberg (EKRA, 2000). A second cantonal referendum was held in 2002. This time, 58% of the voters rejected the proposal.

In 1979, the Swedish implementer, SKB, began to execute the deep-disposal strategy by drilling and logging dozens of boreholes throughout the country (SKB, 2011). The first investigations, at Finnsjön and Kråkemåla evoked no public resistance. When the studies expanded in 1980 to Kynnefjäll, however, opponents constructed a guard hut obstructing the only path leading to the proposed drill site. The hut is pictured below in Fig. 2. SKB's subsequent efforts in Svartboberget, Klipperås, and Almunge also were frustrated. The national media reported extensively on these protests, leading the Minister of Energy and Environment to reprimand SKB for creating a confrontation and for not properly informing the affected communities in advance of its plans.

It was not until 1987 that Great Britain and France began their search for a deep-mined, geologic repository site (Kemp, 1992) and (Cotton, 2017). The British focused on the disposal of intermediate-level radioactive waste. (The rationale for this focus derived from a belief that by the time it was disposed, HLW would have decayed to ILW.) As part of *The Way Forward* project, the implementer, Nirex, elaborated a nine-step strategy that ultimately winnowed nearly 500 potential sites down to two: Dounreay in Northern Scotland (near an experimental breeder reactor) and the Sellafield complex in west Cumbria, the location of the country's weapons-material production and reprocessing facilities. The selection of those two sites took place in the face of extensive public

Fig. 2 Guard hut at Kynnefjäll. US Nuclear Waste Technical Review Board (2015) *Designing a Process for Selecting a Site for a Deep-Mined Geologic Repository for High-Level Radioactive Waste and Spent Nuclear Fuel: Detailed Analysis*, p. 101. Washington, DC: NWTRB.

consultations that revealed strong opposition in both communities. Based on evaluations of boreholes drilled at both sites in 1989, the implementer concluded that Sellafield was the preferred location. It submitted a planning application for a Rock Characterization Facility four years later.

The Cumbria County Council argued against the application and, relying on its legal authority, called for a public inquiry. Over a period of five months from September 1995 through February 1996, supporters and opponents debated the environmental impact of the surface facilities and examined the projections of long-term safety. The inquiry's moderator recommended that the planning application be rejected. In March, 1997, the Secretary of State for the Environment upheld that recommendation.

The French implementer, ANDRA, sought to carry out the deep-disposal strategy by investigating potential sites in granite, shale, clay, and salt formations. These were located the Deux-Sèvres, Maine-et-Loire, Aisne, and Ain *départements* respectively. Depending on the locality, between 75% and 95% of voters expressed opposition to the studies even before they began (SKN, 1992). At Deux-Sèvres, ANDRA was forced to use aerial surveys after ground survey lines were slashed. At Maine-et-Loire, 400 armed police were called out to quell a demonstration. At Ain, opponents seized excavating equipment and burned documents after entering the local ANDRA office (ERC, 1989).

By 1989, the local and national protests had become so disruptive that the central government declared that the communities must cooperate with ANDRA's efforts. Those pronouncements were of little effect. If anything, they prompted the demonstrators to intensify their campaigns. In early 1990, having just met with politicians and local opponents from Maine-et-Loire, Prime Minister Michel Rocard announced a yearlong moratorium on test drillings at the four sites.

In 1994, the Canadian implementer, Atomic Energy of Canada Limited (AECL), released a detailed environmental impact statement to support the deep-disposal strategy by constructing a repository in the crystalline rock of the Canadian Shield (AECL, 1994). Public hearings began two years later, and a report to the Canadian Government was published in 1998 (Seaborn, 1998). The key conclusion of the report held:

From a technical perspective, safety of the AECL concept has been on balance adequately demonstrated for a conceptual stage of development, but from a social perspective, it has not. As it stands, the AECL concept for deep geological disposal has not been demonstrated to have broad public support. The concept in its current form does not have the required level of acceptability to be adopted as Canada's approach for managing nuclear fuel wastes.

In late 1998, the Canadian Government accepted the panel's advice.

Notwithstanding Japan's deep commitment to nuclear power as an energy source, the Japanese nuclear waste-management program got off to a slow start. Coming belatedly to waste-management policymaking did have one advantage: lessons learned from other national programs, especially the importance of the social acceptability filter could be incorporated into the plans to site a repository.

The Diet passed the Specified Radioactive Waste Final Disposal Act in 2000. Two years later, the implementer, NUMO, invited more than 3000 municipalities to learn more about the possibility of hosting a deep-mined, geologic repository. NUMO proposed a three-stage siting process through which potential sites would be winnowed down to candidate sites. It also set forth conditions that would exclude further consideration of specific sites.

Nine communities initially expressed some interest in accepting NUMO's invitation. All but one, Toyo Town on the southeast coast of Honshu Island, soon lost their enthusiasm. In early 2007, the Mayor informed the relevant governmental body, the Ministry of Economy, Trade, and Industry (METI), that it was willing to proceed. Immediately thereafter, the Governor of the Kochi Prefecture, where Toyo Town is located, travelled to Tokyo to voice his strong disapproval. Within weeks, 60% of the municipality's residents signed a petition to recall the Mayor. As one of his first acts, the new Mayor withdrew the town's acceptance.

In sharp contrast to these experiences, the Finnish implementer, Posiva, has largely been successful in passing its chosen repository site in the Eurajoki Municipality through both the technical suitability and social acceptability filters. The process for finding a repository site in Finland was established in 1983. According to the plan, screening studies throughout the nation would be conducted for two years. Preliminary site investigations would take another six years. Detailed studies would be carried out at least five locations. The final choice would be submitted to the Finnish Parliament and the *situs* municipality for their approval shortly before the end of the century. With little variance, those milestones have been met (Posiva Oy, 2019).

In 2015, the Finnish regulator granted the license to construct the repository (STUK, 2015). Posiva subsequently announced that it expected to commence repository operations in 2025 or 2026. Section “What have we learned? What does the future hold?” below discusses why Finland has proven to be a special case.

Why is social acceptability so problematic?

An extensive literature has documented public attitudes regarding nuclear waste in general and repository siting in particular. (With respect to the United States, see, for example, Slovic (1991) and Dunlap et al. (1993). In 1998, 2001, 2005, and 2008, the European Commission sponsored a series of surveys that focused on the question of nuclear waste management. See, for example, European Commission (2008).) Two pieces of research are especially noteworthy for providing insights into the complex interactions of factors influencing the social acceptability of a repository.

The first study advanced a structural equation model based on the results of a telephone survey of Nevada residents probing their support or opposition to the proposed Yucca Mountain repository (Flynn et al., 1992). The most important path, from “trust” to “opposition,” is shown in red. The reader should note that economic benefits played little role in determining support or opposition to the proposed repository (Fig. 3).

Based on a mail survey of the Swedish population residing near proposed repository sites, the second study examined support for or opposition to a local repository (Sjöberg, 2004). Unlike Flynn and his colleagues, the author did not construct a structural equation model but only reported standardized regression coefficients. Because of the sample’s size (2548 respondents), virtually all of the independent variables examined were statistically significant. The four most important, however, were (in order): dread of nuclear waste, benefits from the repository, attitudes toward nuclear power, and trust in the management of SKB.

In addition to these quantitative studies, investigators have carried out qualitative case studies to understand local reactions to the prospect of developing a repository nearby. One inquiry, for instance, examined local responses to efforts to site a repository in France (Mays, 2004). Another considered how Canadian localities were responding to NWMO’s siting activities (Ramana, 2013).

Both the quantitative and qualitative analyses suggest that a number of factors, singly and in combination, can give rise to challenges to the deep-disposal strategy based on social (un)acceptability. These include:

- Contested technical claims—Are data collected or are the models constructed disputed?
- Public perceptions—What does the public believe about the risks that a repository poses? Does the facility’s presence stigmatize the communities?

Fig. 3 Opposition to the Yucca Mountain repository. The numbers refer to standardized regression coefficients. Flynn J., et al. (1992). Trust as a determinant of opposition to a high-level radioactive waste repository: Analysis of a structural model. *Risk Analysis* 12(3): 417–429.

- **Mistrust**—Are the implementer and regulatory authorities credible?
 - **Inequitable processes and decision-making power**—Are the decision-making processes considered fair and just? Are interested and affected parties given some decision-making power?
 - **Opposition toward nuclear power**—Should nuclear reactors continue to operate?
- Other, less systematic factors that might contribute to social (un)acceptability are (1) the presence on an intermediate jurisdiction (state or province) between the central government and the locality and (2) a clear prohibition for accepting foreign HLW and SNF.

Contested technical claims

In the United States and Germany, contested technical claims undermined the social acceptability of the deep-disposal strategy. In the early 1970s, the AEC's plans to develop a repository in Lyons, Kansas, ran into two technical complications. Large quantities of water used for solution mining of the salt in an adjacent location could not be accounted for. The locations of some of the boreholes drilled to explore for oil and natural gas were unknown (De la Bruheze, 1992). Fifteen years later, the State of Nevada strongly rejected DOE's claims about the technical suitability of the Yucca Mountain site. When the implementer filed a license application to construct the facility, the state countered with nearly 400 contentions that it sought to adjudicate (Adams, 2010).

Attacks were mounted as well about the technical suitability of the Gorleben site. Critics in particular called attention to the so-called "Gorleben channel," a geologic structure that could degrade and erode the overlaying rock of the salt dome (Hocke and Renn, 2009).

Risk perceptions and stigma

The historian Spencer Weart persuasively documented why the general public looks at things nuclear through a very different lens than it perceives other technological hazards (Weart, 1988). Those perceptions and the possible stigmatization of localities that might arise therefrom are termed "special effects." (These effects stand in contrast to "standard" effects, which can arise from both nuclear and non-nuclear projects. Such impacts include, among other things, changes in the tax base, employment level, water and air quality, and housing stocks.)

Psychometricians and sociologists have provided strong evidence that the general public believes the risks associated with the disposal of radioactive waste are significantly higher than the risk calculated by the scientific and technical communities (Slovic, 1987, 1991; Sjöberg and Drottz-Sjöberg, 2009). Those specialists generally bemoan and grumble that such a difference persists, although recently they have accepted that the difference is an important reality that needs to be acknowledged. Such an acknowledgment appears to be a prerequisite to effective communication with interested and affected parties.

The two quantitative studies noted above suggest the influence of risk perception and stigma on the social acceptability of repositories in the United States and Sweden. But case studies provide support for the claim that those perceptions have influenced to varying degrees the social acceptability of repositories elsewhere. In France, for example, the potential site in Ain was originally called "Bresse." Bresse chickens and cheese, however, are especially valued in France. Local farmers were concerned that a nearby repository would stigmatize those agricultural products and reduce their value (ERC, 1989). Yet, even a change in the name of the potential site did not extinguish fears about the possible taint of the localities. In Germany in the early 1970s, the Lower Saxony Ministry of Agriculture objected to examining salt formations, complaining that releases from a repository would stain the reputation of locally produced foods.

Mistrust

The quantitative studies also highlight how trust in the implementer affects the social acceptability of a repository projects in the United States and Sweden. But once again the case studies suggest the important role trust plays in other countries. In Great Britain, the implementer Nirex, not only failed to obtain planning permission to construct the Rock Characterization Facility, but the company's behavior as revealed in the public inquiry permanently damaged its credibility (Cotton, 2017). ANDRA's then-incorporation into the French Atomic Energy Commission made it harder to secure the trust of the communities when it sought to investigate potential repository sites in the late 1980s. After a series of hearings beginning in 1979, the Prime Minister of the State of Lower Saxony announced the selection of the Gorleben repository site. But he prevented the release of any report documenting the basis for the selection. His expectation that trust in his judgment would be sufficient for social acceptability proved to be unfounded (Hocke and Renn, 2009).

Inequitable processes and distributions of decision-making power

Through the 1980s, efforts to effect the deep-disposal strategy lacked transparency and paid little or no attention to the wishes, views, and opinions of most interested and affected parties. Concerns raised about the fairness of the process and how power was distributed contributed to the (un)acceptability of the deep-disposal strategy as well.

In Germany, France, Sweden, and the United Kingdom, the implementers were at first given free rein to identify and investigate potential sites for a repository. Although they had to keep governmental authorities informed of their activities, those bodies were

not required to approve of the implementers' choices. Nor, of course, were localities given the power to object to any particular site. In fact, often communities first learned about the implementers' interest when drilling crews arrived. Not surprisingly—except perhaps to the implementers themselves—once the plans became public, widespread protests arose in all those countries.

In the United States, inequitable processes and distributions of decision-making power strongly motivated the State of Nevada's opposition to the proposed Yucca Mountain repository. As noted above, the 1982 legislation to structure the site-selection process called for technical studies to compare the viability of at least three possible sites. In 1987, Congress amended that law to exclude investigations anywhere other than Nevada. More than 30 years later, the state's supporters still refer to the amendments as the "screw-Nevada bill" (Adams, 2010)."

Opposition to nuclear power

The inextricable connection between the production of nuclear-weapons material and nuclear electricity on the one hand and the management of HLW and SNF on the other provides grounds for certain groups to reject the deep-disposal strategy. In some nations, activists sponsored demonstrations aimed at blocking the development of a repository in the hope of shutting down nuclear power reactors of all types. The reasoning imputed to those parties suggests that resolving the nuclear waste management issue would reduce or eliminate one rationale for opposing continued production of nuclear electricity. In Canada, Great Britain, Switzerland, and the United States, it is unclear how much anti-nuclear movements, *per se* influenced the social acceptability of the deep-disposal strategy. See, for example, Touraine (1983), Cotton (2017), Carter (1987) and Ebbin and Kasper (1974).

But in Sweden and Germany, those advocates have been joined by large segments of the general public. In the former country, the link between nuclear power production and nuclear waste management was the subject of a national referendum held in 1980 (SIFO, 1980; Sunqvist, 2002). The options presented in that plebiscite did not permit a straightforward "yes/no" vote. One option was to allow the reactors operating or under construction to continue to be used until renewable energy sources came on line; it secured roughly 20% of the vote. A second alternative called for at least a partial phase-out; it received nearly 40% of the vote. The third option required a more rapid total phase out; it also collected nearly 40% of the vote. The Swedish Government chose to interpret the results of the referendum as calling for a gradual phase-out. This sharp division among the general population has become somewhat attenuated over time. Nonetheless, Sjöberg (2004) clearly documents the lasting effects of attitudes toward nuclear power on the social acceptability of the deep-disposal strategy.

In Germany, opposition to nuclear power generation has a long and controversial history (Nelkin and Pollak, 1982). Anti-nuclear activists were well-represented at the demonstrations that took place around the Gorleben site. They also led the legal fight against the Konrad repository for medium- and low-level waste. The bulk of the protestors who blocked the repatriation of German utility-owned HLW from the French reprocessing plant at La Hague were part of the anti-nuclear movement. A general consensus has formed around the idea that the German nuclear waste-management program had been held hostage to the politics of nuclear power for nearly a half century (Hocke and Kallenbach-Herbert, 2015).

Reconstructing the deep-disposal strategy

By the end of the 1980s, it had become clear that the deep-disposal strategy, as formulated by the NAS panel, had become socially unacceptable among countries with strong pluralist and democratic traditions. (Other scholars give the label "deliberative turn" to this period. See, for example, Olliges (2019).) Attempts to locate a potentially technically suitable repository site had been contested and blocked time and time again. An awareness took hold in the halls of governmental authorities and in corporate board rooms that repeating past efforts would likely lead to the same failed result. Thus, over the next 25 years, France (1991), Sweden (1992), Canada (2002), Japan (2002), Great Britain (2006), Switzerland (2008), United States (2010), and Germany (2013) began the process of reconstructing the deep-disposal strategy. Common in all those nations was the recognition that the social acceptability filter had to be strengthened and had to occupy a more central role in the siting process. The effort to reconstruct the deep-disposal strategy in each country is discussed below in roughly the order that it took place.

Shaken by the demonstrations that erupted at each proposed site, the French Parliament passed the 1991 Nuclear Waste Act. The main provisions of that law were (Barthe and Meyer, 2012):

- The exploration of new research options became a requirement. In parallel with studies on irreversible and reversible geological disposal, two other alternatives were explored: processes to destroy the long-lived elements in nuclear waste (separation and transmutation), and solutions for storage above ground.
- Local communities have to agree before the implementer could construct an underground research laboratory (URL).
- New procedures were established to improve information and debate.
- New ethical principles were asserted, such as the protection of nature, the environment and health, as well as the rights of future generations.
- At least two different rock formations had to be characterized for the URL.

Over the next four years, ANDRA focused its efforts to site a URL in the Gard, Vienne, Meuse, and Haute-Marne *départements*. The wine producers' fears of stigmatization ultimately led to Gard's exclusion; Vienne proved to be technically suspect. In Haute-Marne, the regional council and the *département* approved the URL's construction, although the Meuse *département* never took a vote. In

early, 1999, ANDRA submitted a license application to construct the facility adjacent to the town of Bure, located near the border of the Meuse and Haute Marne *départements*. The French Government approved that decision six months later.

In 2005, the implementer prepared a dossier supporting the choice of an argillite formation underlying Bure (ANDRA, 2005). (Since the crystalline rocks near Vienne were technically compromised and no other community sitting atop such formations was prepared to volunteer, ANDRA compared the Bure site with an abstract granitic site.) A public debate was then held, out of which came the recommendation that any deep-mined geological repository must be designed to be “reversible.” (I thank Christophe Poinssot for this comment. “Since the basis for defining the concept of deep geological repository was to find a site suitable forever, what reversibility could mean? I think it is a very good example of the necessary hybridization between technical criteria and suitability, and social criteria and acceptability. For sure, an irreversible deep repository is from the experts’ point of view safer, but from the citizens’ point of view, a repository can hardly be accepted if it is not reversible. Reversibility was therefore introduced by the society as a kind of compromise to find a midway path between both positions.”) In 2006, Parliament ratified this condition, thereby establishing a new deep-disposal strategy. That same law specified that the repository for long-lived intermediate-level waste and HLW would, in fact, be located in the region surrounding Bure. After a contentious public debate, Parliament passed the Act of 25 July 2016, which set the terms of construction for the repository and detailed the conditions required for reversibility.

In 2017, a critical report prepared for the Nuclear Safety Authority expressed reservations about the chemical reactivity of packages of bituminous waste, which would be co-disposed in the repository. A 2021 report from the French Environmental Authority also questioned whether ANDRA’s reversibility strategy was sufficient. Studies to resolve those concerns have pushed back plans to submit a construction authorization from the original 2018 date.

By all accounts, ANDRA has successfully embedded itself within the local communities. It has underwritten major development projects, including those upgrading the transportation infrastructure and improving the attractiveness of the area. Its engagement with local advisory committees (CLIs) has largely been productive. Yet, demonstrations involving as many as 500 “pinprick protesters” continue to take place around Bure. Even so, there is certainly no indication that the French nuclear-waste management program is likely to change course.

After the resistance it encountered from targeted municipalities in the late 1980s, the Swedish implementer, SKB, paused its site-specific geologic studies. However, by then, it had concluded that many locations were “good enough” to host a repository based on the KBS-3 logic (Daoud and Elam, 2012). Moreover, SKB determined that even less-than-perfect rock could be engineered to meet the country’s safety standards. Most importantly, the implementer came fully to understand that under Swedish law, municipalities held the final say over whether a repository could be constructed (Swedish National Council, 2014). The NAS panel-inspired deep-disposal strategy was no longer sustainable. SKB’s focus shifted to ensuring that any location ultimately selected would meet the requirements of the social acceptability filter, that is, avoiding a municipal veto.

In sum, SKB now recognized that the success of its siting project depended decisively on finding a willing host community. Also, it became apparent that the old technocratic organization was ill-matched for the social and political environment in which it would now have to operate. As one study observed (NWTRB, 2015):

New leaders were put in place; individuals were rewarded when they formed bonds of trust with local residents; and, as appropriate, officials maintained a strong presence in the municipalities to answer questions and to reinforce the idea that SKB was not necessarily an outsider.

SKB invited all 286 municipalities to host “feasibility studies.” The response was anemic. Two communities in northern Sweden, Malå and Storuman, far away from the nation’s reactors and waste storage facilities, did volunteer. As before, protests arose in each. After the completion of the feasibility studies, the municipalities’ leaders authorized referenda on whether SKB should follow up those initial studies at the sites. In Malå, 71% voted to shut down the investigations; in Storuman 54% objected (Elam and Sundqvist, 2006).

The municipalities’ negative response prompted SKB to prod five nuclear communities—Nyköping, Oskarshamn, Östhammar, Varberg, and Kävlinge—to come forward. The first and the last two never pursued the matter. But, subsequently, three neighboring municipalities—Älvkarleby, Hultsfred, and Tierp—accepted the implementer’s invitation. For reasons both technical and political, in the end, only Oskarshamn and Östhammar remained in the hunt. It should be noted that Oskarshamn and Östhammar are communities where SKB’s owners operate nuclear power plants. In 2011, SKB selected the latter site for the final repository and the former for the required SNF encapsulation plant. Östhammar’s leadership has tacitly supported the construction of a repository throughout the siting process, unlike Oskarshamn’s, which was more vocal in its support. But the Östhammar Municipality unwilling to make a formal commitment until the central government reviewed SKB’s license application.

That review was two-pronged. The safety authority had to decide whether the application met the requirements of the Nuclear Activities Act; an especially appointed Land and Environmental Court had to determine whether the application fulfilled the conditions of the Environmental Code. In 2018, both bodies submitted their advice to the government. The safety authorities’ recommendation was positive; the court’s was negative, holding that there were unresolved questions regarding the longevity of the waste package. Those uncertainties needed to be better evaluated before the repository could be constructed. (The Land and Environmental Court never prepared an official English translation of its decision. An unofficial one was released by MKG, an advocacy organization that opposes approval of SKB’s license application (MKG, 2018)).

In 2019, SKB submitted to the Swedish Government additional technical studies designed to address the Environmental Court’s concerns. That same year the Oskarshamn municipality formally voted to approve the license application for the encapsulation plant. The Environmental Court then revisited its earlier decision and determined that the final repository would, in fact, satisfy

the requirements of the Environmental Code. In November, 2020, the Östhammar municipality agreed to support to license application. As of early 2021, license approval awaits a decision by the Swedish Government.

When AECL's technology-driven approach failed to gain social acceptance in 1998, Canada's government considered a variety of alternatives for moving forward. Four years later, it brought into force the Nuclear Fuel Waste Act. That legislation transferred the responsibility for selecting a repository site from the Crown Corporation AECL to the nuclear power plant owners. That group was instructed to recommend a new deep-disposal strategy that would merit social acceptability.

The new implementer, the Nuclear Waste Management Organization (NWMO), announced that its mission was to "develop collaboratively with Canadians a management approach for the long-term care of Canada's used nuclear fuel that is socially acceptable, technically sound, environmentally responsible, and economically feasible (NWMO, 2005)." NWMO focused sharply on ways to ensure community well-being, a prerequisite for encouraging localities to come forward and participate in the siting process.

And participate they did. Initially 22 communities expressed an interest in learning more about the implications of hosting a deep-mined, geologic repository. They consented to desk-based studies and preliminary site investigations. By the end of 2019, NWMO had deselected all but two possible locations—South Bruce and the area around Ignace. NWMO ended its involvement in the other 20 sites because of concerns that they could not successfully pass through the technical suitability filter. But in several cases, the implementer also concluded that constructing a repository would create fissures within the locality and thus would detract from community well-being, making it unlikely that those locations could pass through the social acceptability filter. Importantly, the leaders of none of the 20 potential sites withdrew from the process on their own volition (NWMO, 2019).

The situation may have potentially changed as the new decade arrived. The majority owner of NWMO, Ontario Power Generation (OPG), had proposed to construct a repository for low- and intermediate-level waste in Bruce, which was the location of several of its nuclear power plants. In January, 2020, 85% of the Saugeen Ojibway First Nation voted its disapproval. Fulfilling its longstanding promise, OPG announced that it would not develop that repository without a willing and informed host and that it would seek alternative solutions. The implications of this development for NWMO's site-selection process for SNF are not clear at this time; the Saugeen Ojibway are also heavily involved in that activity. In any event, NWMO reports that its interactions with the Ignace community are intensifying.

With the collapse in 2007 of NUMO's initiative to engage a willing community potentially interested in hosting a repository, the Japanese implementer stepped back to reassess its approach. Its first response was to enhance its so-called "public acceptance" activities. When that tact yielded no results, NUMO hinted that it might target specific municipalities.

The 2011 tsunami that destroyed the Fukushima-Daiichi reactors fundamentally changed the political and social environment with respect to nuclear power in general and nuclear-waste management in particular. The Science Council of Japan, the equivalent of the NAS, cautioned that NUMO's approach was fundamentally flawed. "There is a limit to what we can do with currently available scientific knowledge and technological capacities to search out geological formations that will remain stable of tens of millennia." The Japanese Government rejected the Council's advice. METI maintained that it would play an active role in choosing a permanent place. More specifically, it would abandon the current system of waiting for volunteers to raise their hands.

That aggressive stance moderated over the next few years. METI published a map delineating areas that would likely fail to pass through any technical suitability filter. These included locations near active volcanos and faults and adjacent to natural resources. Potentially suitable areas, especially with regards to transportation, were found mostly along the coasts of each Japanese island. Using the map, NUMO conducted a series of symposia and "Dialogue-Based Explanatory Meetings" throughout Japan. By the end of 2020, more than 100 consultations had taken place. Then in late 2020 two communities, Sutto Town and Lamoenai Village, accepted NUMO's proposal to conduct literature surveys.

The failure of Great Britain's implementer, Nirex, to obtain planning permission for a Rock Characterization Facility shattered that nation's waste-management program. In its wake, the government established an independent Committee on Radioactive Waste Management (CoRWM) to review a broad range of long-term strategies. The Committee's advice focused on laying out the requirements for a radically different social acceptability filter (CoRWM, 2006). It stressed the

- Importance of continuous public and stakeholder engagement
- Principle of volunteerism
- Need to develop partnerships between the community and the implementer
- Right of withdrawal from the process
- Requirement that key decisions be ratified by democratically elected local bodies.

Two years later, the British Government published a *White Paper*, in which it accepted those recommendations (DEFRA, 2008). Although feelers were extended to other communities, only the Cumbria County Council and two boroughs in west Cumbria, Allerdale and Copeland, were prepared to form a partnership. That alliance worked hard for nearly four years to evaluate the impacts of hosting a repository. It forwarded its comprehensive report to the three governmental participants in the partnership (West Cumbria Partnership, 2012). Under rules stipulated by the Government, all those local authorities had to agree ("three green lights") to move the process forward. In 2013, the two boroughs did; the county council did not.

The next year the Department of Energy and Climate Change issued another *White Paper* announcing changes to the process for siting a repository (DECC, 2014). Presented as a "lessons-learned" document, it advanced several important new policies.

- A National Geological Screening would be carried out to identify in advance sites that were potentially suitable.
- Local communities would lose their planning-permission authority. Boreholes for investigating sites and the repository itself would be subject to national land-use planning.

- Communities would be allowed to withdraw from the process up until the point when a “test of public support” is taken.
- Specific monetary benefits for participating in the process would be provided.

It is noteworthy that the word “partnership” cannot be found in the report. Moreover, important questions, such as what constitutes a community, what is a test of public support, and what authority should exercise the right of withdrawal, were left to the deliberations of a Community Representation Working Group. That body met regularly but never released a formal report.

In late 2018, the Department of Business, Energy, and Industrial Strategy, released a series of policy papers that attempted to address those lingering questions (BEIS, 2018). Working Groups (community partnerships) once again became the main object of engagement. If established, they would have to include at least one “relevant principal local authority,” be it a county or borough council. Importantly, the Working Groups would have sole responsibility for making recommendations to relevant principal local authority/ies on whether to invoke the right of withdrawal and if and when to hold a test of public support. Further, the Working Groups would determine the mechanism for that test, such as a local referendum, a formal consultation process, or statistically representative polling. If there are multiple relevant local authorities in the group, all must agree to hold the test. No single local authority would be able to unilaterally exercise the right of withdrawal. (The policy papers do not indicate how disagreements among the relevant principal local authorities should be resolved. This was the central stumbling block that doomed the West Cumbria Partnership in 2012.) In late 2020 and early 2021, the implementer (now Radioactive Waste Management Ltd [RWM]) announced that working groups had been formed in Copeland and Allerdale respectively. It remains to be seen whether other communities will join the two west Cumbrian boroughs, which had been active for more than a decade.

For the most part, the Swiss nuclear waste-management program has progressed at a deliberate and measured pace. The implementer, Nagra, explored potential sites in crystalline rock but formally abandoned that approach in 2004 for technical reasons. It then focused its attention on locations overlying Opalinus clay formations in the north, publishing a report that detailed a safety case for a repository constructed in that host rock (Nagra, 2002). The OECD’s Nuclear Energy Agency gave the analysis a strong positive review (Nuclear Energy Agency, 2004). Nagra recommended that a site in the Zürcher Weinland be chosen.

The Federal Council concluded that the safety and engineering feasibility of such a disposal facility had been demonstrated. But it maintained that a choice of one site was no choice at all. It asked the Federal Office of Energy to develop a more comprehensive, transparent, and participatory siting process. That agency released its Sectoral Plan in 2008 (SFOE, 2008).

A multistage effort began. Over time, technically suitable regions were identified. Increasingly, local communities became more involved in selecting the location for the repository’s surface facilities, although at least formally they have no role in shaping the postclosure safety assessment of the repository itself. Moreover, the cantonal veto, exercised in Wellenberg, was replaced with the possibility of a national referendum. To date, five potential regions have been winnowed down to three: Zürich Nordost, Nördlich Lägern, and Jura Ost. Nagra at first proposed drilling test boreholes only in Zürich Nordost and Jura Ost. The regulatory authority recommended that boreholes should be drilled in Nördlich Lägern as well. In early 2018, the Federal Council approved that recommendation. Several boreholes have been drilled to evaluate the subsurface characteristics of the three potential regions; some of them yielded unpleasant surprises about the quality of the rock. Based on the results of the geoscientific investigations, Nagra will announce the site or sites for which it will prepare general licence application sometime around 2022. It expects to submit the application by 2024. Although concerns have been raised at various stages, the new deep-disposal strategy appears to have largely secured broad social acceptability.

In accord with the 1987 Nuclear Waste Policy Amendments Act, the United States Congress in 2002 approved President George W. Bush’s recommendation to select the Yucca Mountain site as the nation’s first repository for HLW and SNF (Congress, 2002). In 2008, DOE submitted to NRC a license application to construct a repository. The regulatory agency’s staff began to conduct a series of adjudicatory hearings to review the application. In 2010, DOE sought to withdraw the application. (The unit within DOE responsible for developing a repository had been disbanded.) Although it cited no technical reasons for this action, the DOE Secretary declared that the Yucca Mountain project was “unworkable,” an unmistakable reference to Nevada’s implacable opposition. Several rounds of litigation followed, both at the NRC and before the Court of Appeals for the DC Circuit. In the end, NRC was ordered to spend the small amount of appropriated funds that remained. This enabled the regulatory staff to complete a *Safety Evaluation Report* for the repository.

President Barack Obama in 2011 directed DOE to empanel a Blue Ribbon Commission on America’s Nuclear Future (BRC) to evaluate policies for managing the back-end of the nuclear fuel cycle. The BRC’s *Final Report* appeared 2 years later (BRC, 2012). Its centerpiece was the recommendation that “a new consent-based approach to siting future waste-management facilities” be adopted. Legislation was introduced to authorize many of the elements found in the BRC’s report. None passed. And, although the administration accepted virtually all of the BRC’s advice, it delayed nearly three years before it seriously attempted to initiate programs to effectuate the Commission’s ideas.

In 2017, with the advent of the Trump Administration, focus shifted away from the BRC’s report. Policymakers (once again) turned their attention to promoting centralized interim storage facilities, either private or public. President Donald Trump continued to request funding to restart the Yucca Mountain licensing hearing. The House of Representatives consistently supported the budget request. Those bills, however, never got through the Senate.

In 2020, the administration stopped asking for money to reconvene the NRC’s review. The President tweeted that he heard the “voices of Nevada’s and that his Administration will RESPECT [sic] you.” Although the President indicated that “new innovative approaches” would be explored, it was never made clear what they might be. Other than announcing its opposition to licensing the Yucca Mountain-repository, the Biden Administration has not yet set forth a new waste-management policy. Thus, lack of social acceptability doomed whatever remained of the nearly half-century old nuclear waste management program in the United States.

In 1999, after the Social Democratic and Green Parties took over the reins of government in Germany, they appointed a Committee on a Site Selection Procedure for Disposal Sites (AkEnd, 2002). The government instructed the committee to start with a blank “white map” of Germany and to develop a process for siting a single repository that would take all forms of radioactive waste. The committee proposed an elaborate set of qualifying and disqualifying conditions to winnow down potential sites. The panel held workshops, public meetings, and numerous meetings with interested and affected parties to obtain their views on how to revise the prevailing deep-disposal strategy. Ultimately, however, the committee failed to convince federal legislators that it was time for a change.

In 2011, after several years of vacillation and in the wake of the tsunami-triggered accident at the Fukushima-Daiichi reactor, the German Government shut down eight nuclear power plants and committed to close the remaining nine reactors by 2022. Once it became evident that this policy would not be reversed, the door was opened for the first time in decades to reconsider the siting of a repository for HLW and SNF.

With substantial multi-partisan support, Parliament passed the Search and Selection of a Site for a Repository for Highly Radioactive Waste Act (StandAG) in 2013. The key provision called for the appointment of a Commission on the Storage of High-Level Radioactive Waste. Its charge was virtually the same one presented to the AkEnd panel. But its conclusions differed in some important respects (NTW, 2017).

- The “best-possible” safety of the repository should be ensured for a period of 1,000,000 years.
- The site-selection process should start with a blank map of Germany. (This language was adopted to allow the Gorleben site to be included in the search. It also meant that sites possessing host-rocks other than salt, such as clays and granites, had to be evaluated.)
- The Bundestag should ratify each of the five steps specified in the site-selection process.
- The repository should be designed to be reversible.
- Extensive and robust participatory procedures should be scrupulously followed, although the selected community would not have the formal authority to veto the choice of site.
- New implementing and regulatory agencies should be established and their credibility should be tightly guarded.

In 2017, the Parliament amended the StandAG to incorporate almost all of the Commission’s recommendations.

Even before then, Germany embarked on the extraordinarily demanding task of fundamentally restructuring its nuclear waste-management program. A new implementer, the Federal Company for Radioactive Waste Disposal (BGE), and a new regulator, the Federal Office for the Safety of Nuclear Waste Management (BsE), were established. The operations of low-level disposal facilities at the Asse II mine, Morsleben, and Konrad were consolidated under BGE. In addition, the implementer created the National Advisory Board, an independent body that would monitor the siting process to ensure that the public’s best interests were protected. BsE started the long process of completely revamping its waste management regulations to accommodate the possibility that a site in clay or crystalline rock might have to be evaluated. In particular, it realized that new regulations that would have to be adopted that permitted the comparison of sites in different host rocks.

The site-selection process gained momentum over the next three years. In late 2020, BGE published an analysis that evaluated the “blank map” against the exclusionary criteria contained in the Commission’s report. It concluded that Germany’s total high-activity waste could be disposed in 15 out of the 16 states in 90 areas covering 54% of the country. Among those locations eliminated was the Gorleben site because of its potential for erosion.

Most observers have concluded that the legally specified deadlines for site selection (2031) and repository operation (2050) are optimistic. It remains to be seen whether pursuing them over the next few decades will sustain or degrade the current reservoir of social acceptability.

What have we learned? What does the future hold?

In the final section of this article, I reflect on the special case of the Finnish nuclear waste-management program and ask why it avoided all of the disruptions that plagued the efforts in so many other nations. I then evaluate the material presented above and use that information to ponder what might lie ahead.

The special case of Finland

Finland has four operating reactors, two built using Swedish technology and the two built using Soviet technology. Initially, the Soviets agreed to accept the SNF from its plants, so, at its earliest stage, the Finnish waste-management program had only to address the disposal of roughly half of its SNF inventory. In 1997, the Russians abrogated the agreement to repatriate the waste. The Finnish program was revised to accommodate this change in circumstances.

In 1983, the Finnish Government adopted the deep-disposal strategy. It set forth the main goals and milestones for the site-selection program. Several potential sites, whose selection would be based on careful studies of the whole country, would be characterized, and the location for the repository would be selected by the year 2000 (McEwen and Äkäs, 2000).

Between 1984 and 1986, the implementer (now Posiva Oy) screened regional blocks of land and recommended that 101 of them be explored further. The government approved 85. Using the technical suitability filter, these were winnowed down to five

in 1987 including Eurajoki, the location of the two Swedish-designed reactors. A decade later, after the agreement with the Russians was terminated, a sixth site was added at Håstholmen, the location of the Soviet-designed reactors. An environmental impact assessment was prepared that down-selected the number of sites from six to two (Posiva Oy, 1999). Relying on this assessment, which explicitly considered the social acceptability filter, the implementer recommended that Eurajoki be chosen. In 2001, having obtained the consent of the municipal government, the national government passed a “Decision-in-Principle,” officially picking Eurajoki. In 2012, Posiva Oy submitted an application to construct the repository to its regulatory authority, STUK. In 2015, the authority approved the application, and construction commenced a year later (STUK, 2015). Initial operation of the repository is expected to begin in 2025.

The concatenation of five factors that often blocked the passage of sites through the social acceptability filter in other nations never materialized in Finland.

Contested technical claims: The safety cases advanced by the implementers in Sweden and Finland are virtually identical, relying as they do on an updated KBS-3 logic. Yet, in Sweden, SKB continuously had to respond to technical attacks directed at its modeling of the corrosion of the copper canister. In Finland, those challenges were weak and intermittent at best.

Public perceptions: Posiva Oy commissioned opinion surveys at all six potential sites. Not surprisingly, the most welcoming locations were the two nuclear sites. The choice of these communities not only softened negative perceptions, but also promised significant material benefits in the form of property tax payments that covered a substantial portion of the municipal budget (Kojo, 2009).

Meriting and sustaining trust: Although data relating to trust in Posiva Oy is scattered and anecdotal, evidence is strong that the citizens of Eurajoki held STUK in high regard and respected its judgments (Choi, 2018).

Inequitable processes and distribution of political power: Notable is the situation in Finland that the plan governing the waste-management program retained its legitimacy for nearly two decades. The implementer never experienced fierce objections to what it proposed. Moreover, by a 20-7 vote, the Eurajoki Municipality’s concurred with the 2001 Decision-in-Principle.

Opposition to nuclear power: Intense parliamentary debates took place in 1993 surrounding the decision to forego building a fifth nuclear power plant. But those fights barely spilled over into the larger public arena, a sharp contrast to the bitter battles over nuclear power a decade earlier in Sweden. Indeed, without much controversy, parliament approved a fifth reactor nearly a decade later (Lammi, 2009).

Prospects

Overall, it is undeniable that national nuclear-waste management programs have made considerable progress in tackling the social-acceptability issue over the last twenty years; efforts to reconstruct the deep-disposal strategy have been largely but certainly not completely successful.

The technical basis for safe disposal of HLW and SNF in crystalline and a variety of clay host-rock formations has been established in principle. (See, for example, these international peer reviews of disposal strategies in a variety of host rocks: Nuclear Energy Agency (2004, 2006, 2012).) To be sure, non-governmental advocacy organizations in Sweden still contest the viability of the KBS-3 method. The State of Nevada maintains its position that the Yucca Mountain site is technically unsuitable and that DOE’s license application to build a repository there ought not to be approved. Nonetheless, in most countries, contested technical claims rarely drive the (un)acceptability of geologic disposal.

In two respects, however, the newly reconstructed German waste-management program probably represents the test case of whether an implementer can avert strongly contested technical claims from undermining the acceptability of its activities. First, it will be closely scrutinized on how it assesses the technical suitability of the controversial Gorleben site. (As noted earlier, the “blank map” assessment excluded it.) Second, the program will also be judged on how it lays a strong technical foundation for evaluating specific sites not only in salt but also in crystalline and clay formations, host rocks that hitherto have not been a focus of research and engineering.

Unquestionably, public perceptions of the risks that HLW and SNF pose and the stigma they evoke will continue to be more negative than the views held by technical specialists. Implementers have generally acquiesced to this fact of life. Their response has been to focus repository-siting efforts, not always successfully, on nuclear communities (Eurajoki, West Cumbria, Yucca Mountain, Östhammar) or economically underdeveloped areas (Bure and northern Ontario) where the negative perceptual beliefs are counterbalanced by strong positive material benefits. So far, in Canada, Finland, France, Switzerland, and Sweden, that tact seems to have served the programs well. In Great Britain and Nevada, the so-called “doughnut effect” has manifested itself; communities near the sites have been strongly supportive, while larger jurisdictions around them, such as a state and or a county, continue to object.

Meriting and sustaining trust remains a work in progress in every nation. As is now commonly understood, trust must be gained over the long-term, but it can be lost in a moment. Historically, the Canadian, Finnish, Swedish, and Swiss implementers and regulators have mostly done quite well in this regard. Those in France, Germany, Great Britain, Japan, and the United States have much more mixed records. The former group of countries explicitly structures its activities to emphasize the centrality of trust. The latter group, while acknowledging the importance of trust, does not appear to make it the core of their actions. Given that waste-management programs unavoidably must endure for many decades, maintaining trust in all countries remains an open question.

In all the nations discussed in this article, except the United States, the legitimacy of the process for selecting repository sites and developing them has generally gone unchallenged. Part of the reason for this acceptance stems from the enlarged role interested and

affected parties have played and will continue to play in reconstructing the deep-disposal strategy. In Finland and Sweden, the affected municipalities have exercised their near-absolute right to veto the license application to construct the repository. (In the United States in sharp contrast, the State of Nevada sought in 2002 to veto the selection of Yucca Mountain, but its objection was overridden by both houses of Congress.) A different approach has been suggested by the Steering Group of the Reset Project (Reset Group, 2018.) In Canada, France, Great Britain and Japan, communities must affirmatively express interest in hosting a repository and can withdraw from the process up until some pre-determined point. Neither Germany nor Switzerland offer localities the right to veto or withdraw from the siting process. But local governments in both nations have strong participatory protections.

Anti-nuclear sentiments clearly affected the early siting activities in Sweden and continued to shape site-selection efforts in Germany for decades. Those attitudes dissipated once decisions were taken to limit or shut down the operating reactors. To be sure, anti-nuclear protests, such as those experienced in the last two years at Bure, are likely to persist. They are unlikely, however, to reemerge as a decisive factor affecting the social acceptability of geologic disposal.

In sum then, progress in Finland, France, and Sweden almost certainly will continue. In Canada and Switzerland, the steady and deliberative efforts are likely lead to the development of a repository. In the remaining four nations discussed in this article, the prospects are much more clouded. Significant regulatory, technical, and political challenges remain in Germany. Successive *White Papers* detailing a siting process in the Great Britain are still struggling to set out a socially acceptable pathway for finding a community willing to host a repository. In Japan, METI's determination to pursue voluntarism appears deep-seated. Whether it will yield positive outcomes remains an open question. More than a decade of political conflict at the highest levels in the United States has resulted in stalemate and programmatic limbo.

As I noted recently, "It is hard to remain sanguine ... But then, working in the nuclear waste disposal business has always been a vocation that has attracted optimists and visionaries, even if they are too often disappointed (Metlay, 2013)." I now have reluctantly concluded that even optimists and visionaries will need greater patience. More than century of the nuclear age will have passed at the very least before we discharge of our long-standing obligation to future generations to securely isolate HLW and SNF for hundreds of millennia.

The theory and practice of Radiation Protection provide the basis for regulatory requirements that are essential for the safe and beneficial use of many advanced technologies that utilize ionizing radiation. Medical diagnostic protocols, such as Computed Tomography (CT) and Positron Emission Tomography (PET) scans are effective for detecting physiological and biokinetic health concerns, respectively. Electrons, alpha particles, photons, neutrons, and protons are used for both curative and palliative treatment of diseases. Chemical and molecular tracers that are tagged with radioactive isotopes contribute to the understanding of fundamental physical, chemical and biological processes in natural and biological systems. The Spallation Neutron Source (<https://neutrons.ornl.gov/sns>) at Oak Ridge National Laboratory (ORNL) is used for imaging basic structural features of materials, which contributes to improved understanding of material science. Imaging with photons and neutrons is useful for Quality Assurance (QA) procedures that verify manufactured components satisfy specifications. Radiation is used to disinfect spices, to sterilize medical equipment, to cross link polymers, and for various other applications. For example, one of the beam ports of the High Flux Isotope Reactor (HFIR) at ORNL is a source of very low energy neutrons that can be reflected at interatomic distances to investigate molecular structures (<https://neutrons.ornl.gov/hfir>). More detailed information is provided by [Waltar \(2021\)](#) and [Barradas \(2021\)](#).

In addition to medical and scientific benefits derived from the use of radiation, power produced by nuclear fission makes a substantial contribution to the energy infrastructure in the US. According to US Energy Information Administration (EIA; <https://www.eia.gov/outlooks/aeo/>), in 2019, the net US electricity generation was 4161 TWh, which was produced by the following sources: natural gas (1558 TWh; 37%), coal (985 TWh; 24%), nuclear (807 TWh; 19%), wind (296 TWh; 7%), hydroelectric (287 TWh; 7%), solar (73 TWh; 2%), biofuels (31 TWh; ~1%), oil (17 TWh; <1%), and geothermal (16 TWh; <1%). EIA expects an average electricity demand growth of 0.9% per year through 2050. These data show that energy from fission is the largest contributor of carbon-free electrical power in the USA (19%), and it is an established technology that could play a major role in sizable reductions in future emissions of CO₂. Individual coal power plants are reported to generate from 0.58 to 1.59 kg of CO₂/kWh (world-nuclear.org, n.d.), for an average of about 1 kg of CO₂/kWh. Natural gas produces about one-half the amount of CO₂ relative to anthracite coal (epa.gov, 2020); thus, the generation of 807 TWh of energy by fission in the US during 2019 would have displaced about 800 million tons of CO₂ if it had been produced by anthracite coal and about 400 million tons of CO₂ if it had been produced by natural gas. For more detailed information see [Stachowski \(2021\)](#).

All the above-mentioned applications involve the use or generation of radiation and therefore require the theory and practice of Radiation Protection.

Section 7 discusses the main elements of radiological protection that enable the use of radiation emitting sources and facilities for enhancement of quality of life. Articles 00701 “*Ionizing Radiation: Discovery and Dose Quantities*” (Dewji, 2021) and 00702 “*Fundamentals of Health Physics*” (Dewji and Miller, 2021) provide the fundamental quantities and scientific bases for quantifying the impacts of exposure to nuclear radiation and defining radiation doses. Concepts of nuclear physics, radioactive decay, absorbed dose, equivalent dose, and effective dose are introduced and discussed.

Articles 00703 “*Natural and Man-Made Sources of Radiation*” (Miller, Apostolaei, Howard, and Singh, 2021) and 00704 “*Source Terms for Nuclear Reactors Operations, Accidents, and Waste*” (Singh and Wheeler, 2021) describe the sources of exposure to radiation in occupational, environmental and medical settings. These sources include: radioisotopes in naturally-occurring radioactive materials, the nuclear fuel cycle, operations of nuclear reactors, diagnosis and treatment of diseases, industrial and academic facilities, and in radioactive fallout from testing of nuclear weapons.

Methods for monitoring external exposure to radiation are described in Article 00705 “*External Dosimetry*” (Veinot, 2021), and those for internal exposure are presented in Article 00706 “*Internal Dosimetry*” (Snapp and Eckerman, 2021). These articles review standards and regulations applicable to external and internal dosimetry programs, describe the use of human anthropomorphic phantoms commonly encountered in dosimetry programs, and provide a brief summary of algorithms for estimation of radiation doses.

Article 00709 “*Standards to Control Exposures of Workers and the Public*” (Kocher, 2021) focuses on the system of radiation protection developed based on the recommendations of the International Commission on Radiological Protection (ICRP) and National Council on Radiation Protection and Measurements (NCRP). It discusses the justification of exposure (positive net benefit to an

individual or society), optimization of protection (keeping all exposures as low as reasonably achievable [ALARA]), and limitation of dose to individuals. Control of dose to individuals limits the risk of stochastic health effects, such as solid cancers, leukemia, and severe heritable effects, and it prevents non-stochastic (deterministic effects), in organs or tissues.

Practices for controlling exposure to radiation in industrial environments are explained in Article 00713 *“Radiological Control Practices”* (Hansen, 2021). Since actions to further reduce already low radiation doses and risk may introduce or exacerbate other industrial risks, the manner in which target risk reductions are traded for countervailing risk is examined and discussed.

When radiologically contaminated sites previously utilized for medical, defense, or industrial purposes are to be made available for general use by the public, they must be characterized, remediated, and certified for compliance with applicable regulations. These processes are described in Article 00707 *“Instrumentation and Practices for Radiological Assessments”* (Vitkus, King, Altic, Wade, and Ivey, 2021) and in Article 00712 *“Characterization and Release of Contaminated Sites”* (Vitkus, 2021). Computer codes commonly used for calculating radiation doses from residual contaminants are described in Article 00711 *“Computer Codes for Determining Acceptable Levels of Contamination”* (Arnish, 2021). These codes provide the criteria for remediation of contaminated sites.

In some environments, radiation fields are sufficiently high that personnel and equipment must be protected by shielding. General methods for determining the amount and type of shielding in industrial environments are described in Article 00714 *“Radiation Shielding Methods”* (Pevey, 2021), and Article 00715 *“Shielding against Galactic and Solar Radiation in Space”* (Heilbronn, 2021) discusses radiation protection in outer space. Article 00708 *“Emergency Response”* (Marianno, 2021) explains procedures and policies applicable in cases of accidental releases or exposures that exceed regulatory requirements. If a release would be difficult to directly evaluate by personnel, an option for remote surveillance is presented in Article 00718 *“Drones for Radiological Assessment”* (Hackett, 2021).

The U.S. Federal regulations are intended to limit cancer risk via the annual limits on the effective dose and to avoid tissue reactions (deterministic effects) via annual limits on the dose to individual tissues. However, many people are uncomfortable with their perceived risk due to radiation, and this has led to considerable debate about the acceptability of production of power by nuclear fission. One way of addressing this issue is to compare known outcomes from everyday societal activities with known outcomes due to operating various nuclear facilities. Article 00710 *“Risk Tradeoff Analysis”* (Hansen, 2021) analyzes this issue within the framework of risk tradeoff analyses. The health effects based on radiation biology are discussed in Article 00716 *“Health Effects and Radiation Biology”* (Nichols and Byrne, 2021). Data obtained from a collection of cohort studies on the health consequences of exposure to various levels of exposure to radiation, under different conditions, are discussed in Article 00717 *“Estimation of Health Risks from Exposure to Ionizing Radiation”* (Apostoei, 2021). Biological impacts of radiation at the microscopic level are described in Article 00719 *“Microdosimetry”* (Nichols, 2021). Finally, a glossary of terms is presented in Article 00720 *“Glossary”* (Dewji, Kocher and Adadi, 2021).

Introduction

The study of the interaction of radiation with matter—i.e., the mechanisms by which energetic waves and particles deposit their energy—along with the associated observed effects of these interactions, have become foundational in informing recommendations, practices, and technologies implemented in radiation protection science.

Radiation is defined as the propagation of energy through matter and space. Radiation can exist in two forms: electromagnetic waves and energetic particles. Radiation with enough excess energy to cause a valence electron to escape the atom, resulting in ionization of the atom, is classified as ionizing radiation. This acts by removing electrons from atoms and molecules of materials that can include air, water, and living tissue. Damage caused by ionizing radiation occurs by the incident wave (i.e., X-ray, gamma-rays) or particle (alpha, beta, neutron) initiating chemical reactions that, in turn, have deleterious effects on tissue. In the context of health physics and radiation protection, the target molecule of primary interest is deoxyribonucleic acid (DNA) in exposed organs or tissues, as well as any intervening materials (e.g., shielding). Ionizing radiation can be classified as directly ionizing radiation, in which charged particles (i.e., protons, alpha, beta, heavy ions) directly transmit energy resulting in an ionization, or indirectly ionizing (e.g., neutrons, gamma-rays, X-rays), which requires a charged particle intermediary to transfer energy to the medium to cause the ionization. The threshold energy for ionization in water is on the order of 4–25 eV (~7.4 eV for liquid water) (Attix, 2008). Ionization can occur with wavelengths shorter than 320 nm, which includes most of the ultraviolet band, X-rays, and gamma rays. Non-ionizing radiation is radiation that lacks sufficient energy to cause an ionization in tissue, thereby limiting the potential damage from exposure and exists around us in many forms and from many sources.

The discovery of X-rays in 1895 by Wilhelm Röntgen initiated studies in the fields of radiation protection and health physics that enabled us to harness the strength of the atom in medicine, industry, and energy, while limiting the harmful effects from unintended exposures of radiation. The beneficial and detrimental effects of Röntgen's rays were quickly noticed, and within a year of this discovery, diagnostic X-ray radiography had become widely employed.

Following the discovery of X-rays, the field radiation protection developed synchronously as subsequent discoveries and the effects of radiation were revealed. Since the early stages of discovery, radiation was proven helpful in the medical field; although, unexamined uses of radiation were followed by serious injuries to the body, including redness on the skin. Several months after Röntgen discovered X-rays in November 1895, the first case of skin injury occurred in the U.S. In many cases, the damage did not appear immediately on the skin. However, in 1905, evidence linking radiation as a causality of cancer was established (Kang, 2016). Soon after realizing the potential harm of unintended use of radiation to the human body, a series of different protection measures were developed.

Management and limitation of radiation exposure has led to the growth of field of health physics, which is defined as the protection of human beings and the environment from the harmful effects of ionizing radiation while permitting its beneficial applications. Health physicists can further be sub-classified as specialists in radiation protection. Regulations and practices have since evolved for establishing exposure limits to members of the public, as well as occupational nuclear workers. Application areas of radiation protection may include the following:

- 1) nuclear energy fuel cycle;
- 2) industry (oil/gas; blood and food irradiation);
- 3) nuclear medicine;
- 4) space exploration;
- 5) consequence management and emergency response; and
- 6) defense and security.

Discovery of ionizing radiation

Early pioneers

Discovery of X-rays

The discovery of the X-ray on November 8th, 1895 was the unexpected result of experiments by Röntgen using a Crooke's tube. In his investigation, a vacuum-enclosed glass tube, much akin to the cathode ray tube of early televisions, was used to transmit electric current—called "cathode rays"—between two electrodes. Operation of the Crooke's tube resulted in fluorescent excitation of the gas in the tube and glass walls encasing the vacuum. While studying the fluorescence in the tube, Röntgen noticed that during operation of the Crooke's tube, a screen located at a distance from the tube fluoresced in a dark room. Realizing that he had discovered a new phenomenon, he referred to these mysterious rays as "X"-rays. Over the course of the following days, Röntgen had amassed a wealth of information regarding the fundamental properties of these X-rays, including the penetrating power through low density, light materials (paper and wood), as well as heavier and higher density materials (aluminum and tin). **Fig. 1** depicts the X-ray of Röntgen's wife, Frau Röntgen's, hand, demonstrating an obvious medical imaging benefit of these new rays, with the hazardous effects

Fig. 1 X-ray picture of the hand of Frau Röntgen made by Röntgen on December 22, 1895. *Reproduced from Turner JE (2008) Atoms, Radiation, and Radiation Protection. John Wiley & Sons.*

yet to be observed thereafter. This image demonstrated the contrasting degrees of skeletal bone and soft tissue as a result of the differing degrees of absorption of the X-rays in the hand. Röntgen further discovered that X-rays, unlike cathode rays, are not deflected by magnetic fields, and that X-rays cause a charged electroscope to lose charge when interacting with photographic plates (later attributed to the ability of X-rays to ionize air, see “**Exposure**” section). The discovery of X-rays marked the first discovery of ionizing radiation. His discovery was subsequently published in a paper entitled, “On a New Kind of Rays” (Röntgen, 1895, 1896).

Soon after the discovery of the X-ray, it became a prevalent topic of research among scientists in different fields. Scientists throughout the world started studying the nature and effect of X-rays and developed multiple applications for it, especially for medical purposes. However, little research was done on the biological impact of X-rays and scientists were unaware of the side effects that could lead to series of health problems.

Less than a year after Röntgen announced his discovery in November 1896, an American engineer, Elihu Thomson, experimented to determine the potentially harmful effects of X-rays. Thomson exposed his finger to the direct radiation from an X-ray tube daily for a few weeks. For the first week, there was no observable effect, but in the second week, he noticed swelling and pain in his hand and had to terminate the experiment immediately and issued a strong warning against overexposure. Although witnessing apparent deleterious effects, some scientists still denied that the effects were due to X-ray exposure. As for the Thomson’s injury, he thought that the injury was due to a chemical effect within the skin tissues (Kathren, 2019).

Another scientist who conducted research on X-rays was William Herbert Rollins. After the discovery of the X-ray, Rollins spent most of his life performing X-ray-related research and was one of the first pioneers in developing radiation protection measures. Rollins approached every important technique of diagnostic X-ray safety, usually calling attention to a particular source of unnecessary exposure and suggesting to lessen that exposure (Kathren, 2019). American engineer, Wolfram Fuchs, provided the first recommendations for radiation protection in 1896, which have become the tenets of radiation protection: (1) Making the exposure as brief as possible (time); (2) standing greater than 12 in. of the X-ray tube (distance); and (3) covering the skin with Vaseline and add an extra layer on the most exposed area (shielding) (Kang, 2016).

Discovery of radioactivity

Only 2 months following the discovery of X-rays, radioactivity was discovered by Henri Becquerel. Using uranium salt on a photographic plate, Becquerel was able to detect the radioactive rays emitted from the uranium salt. In his investigation, Becquerel exposed potassium uranyl sulfate to sunlight. He expected the uranium salt to emit X-rays from the absorption of the sun’s rays once placed on photographic plates that were wrapped in black paper. The hypothesis was not effectively tested due to cloudy weather in Paris. However, he decided to develop the photographic plates, regardless. Much to his surprise he found clear images proving that uranium emitted radiation without the external energy source of the sun, thereby discovering radioactivity.

Although scientists did not show much interest in Becquerel’s discovery, it marked the beginning of the study of natural radioactivity. The term “radioactivity” was coined by Marie Curie (née Skłodowska). In 1898, following the discovery of radioactivity by Becquerel, Marie Curie together with her husband, Pierre Curie, demonstrated that pitchblende ore showed higher activity than pure uranium, concluding the ore contained other radioactive constituents. This led to the subsequent discovery of two new elements, polonium and radium, both more radioactive than uranium. Although radium was known to destroy tissue, inadequate consideration was given to possible adverse consequences from its unrestricted use. Both Becquerel and Pierre Curie were unknowing victims of the effects of radioactivity, each suffering skin erythema on the abdomen from small samples of radioactive materials carried in their pockets (Kathren, 2019).

The Nobel Prize in Physics 1903 was divided among Antoine Henri Becquerel “in recognition of the extraordinary services he has rendered by his discovery of spontaneous radioactivity,” and the other half jointly to Pierre Curie and Marie Curie “in recognition of the extraordinary services they have rendered by their joint researches on the radiation phenomena discovered by Professor Henri Becquerel,” depicted in Fig. 2 (Nobel Foundation, 2020). The Nobel Prize in Chemistry 1911 was additionally awarded to Marie Curie “in recognition of her services to the advancement of chemistry by the discovery of the elements radium and polonium, by the isolation of radium and the study of the nature and compounds of this remarkable element” (Nobel Foundation, 2020). Marie Curie was the first person to receive the prestigious Nobel Prize twice.

Quantities describing ionizing radiation interactions with matter

The fundamental concepts and quantities used to describe radiation dose are defined as a basis to correlate quantification of radiation physics interactions from ionizing radiation with observed effects and consequences of exposure. These physics interactions lead to the concept of “radiation dose,” defined as the amount of energy imparted per unit mass. In addition to the quantity of absorbed dose, associated fundamental calculable quantities of Kerma and exposure have also been defined by the International Commission on Radiation Units and Measurements (ICRU) (ICRU, 2011).

Dose coefficients¹ can be employed to relate the protection quantities to physical quantities. The International Commission on Radiological Protection (ICRP) defines protection quantities as dosimetric quantities specified in the human body. Protection

¹The use of the terms “dose coefficient” and “dose conversion coefficient” are used here and in the literature interchangeably, representing the same quantities. The term, “dose coefficient” represents updated terminology, as the use of “conversion coefficient” was deemed redundant.

Fig. 2 1903 Nobel Prize in Physics awarded to (Left) Antoine Henri Becquerel, (Middle) Pierre Curie, and (Right) Marie (née Skłodowska) Curie in recognition of the discovery of spontaneous radioactivity.

quantities can be determined by calculation or by a combination of calculations and measurements (ICRP, 1997, 2010). Complementary to the protection quantities prescribed by the ICRP, operational quantities, developed by the ICRU, are intended to demonstrate compliance with protection dose limits by providing calibration quantities for instrumentation measuring or monitoring dose to correlated protective quantities (ICRU, 1998a).

The computation of fluence-to-dose coefficients permits relating a radiation field (operational) quantity, such as fluence (Φ , units cm^{-2}) and its derived quantities (Kerma, exposure), to protection quantities, such effective dose, (E). The relationship between physical, operational, and protection quantities are captured in Fig. 3.

Fluence-to-dose coefficients foundationally relate radiation protection and operational quantities. The recommendations of the ICRP and ICRU, in addition to joint efforts between the two organizations, have led to the computation of dose coefficients aligned with the latest scientific recommendations. The methodologies and tabulations of data of fluence-to-dose coefficients, per the latest international scientific recommendations, are described below and published extensively through a series of reports (ICRU, 1998a, 2011; ICRP, 2007, 2010).

Fig. 3 Relationship between operational and protection quantities. Reproduced with permission from ICRP (1997) *ICRP Publication 74: Conversion Coefficients for Use in Radiological Protection Against External Radiation*. New York, NY: International Commission on Radiological Protection.

Absorbed dose

The absorbed dose, D , is the fundamental unit describing the deposition of energy from ionizing radiation in matter. Absorbed dose can be described in terms of the stochastic quantity, energy imparted (ϵ), as the difference of the radiant energy entering and exiting the volume from uncharged (indirectly ionizing photon and neutron) sources and charged (directly ionizing) particle sources. The absorbed dose is further defined as the quotient of the mean energy imparted by the ionizing radiation into a target volume divided by the mass of the matter in the target volume. The unit of absorbed dose is joules per kilogram (J/kg), which is given the name, gray (Gy) (ICRP, 2007) and sometimes in traditional units of rad ($1 \text{ Gy} = 10^2 \text{ rad}$) or ergs ($1 \text{ Gy} = 10^4 \text{ erg/g}$).

In the system of radiation protection, absorbed dose is the most fundamental quantity and refers to the dose to a specific organ or tissue (T) as (D_T). Modifications to include radiation detriment for different types of source radiation and radiosensitivities are integrated with the fundamental quantity of absorbed dose to evaluate biological effects and establish regulatory exposure limits. It is not possible to write an equation that relates absorbed dose in relation to a deterministic quantity that characterizes the radiation field, as is possible with Kerma, as discussed next. Therefore, fluence-to-dose conversion coefficients can be employed to correlate properties of measurable radiation fields to absorbed dose estimates.

Kerma

Kerma (K) is a deterministic quantity that describes the first step in energy dissipation by indirectly ionizing radiation. The Kerma (kinetic energy release per unit mass) is defined in terms of energy transferred (ϵ_{tr}) to intermediary charged particles in a volume by radiant energies from indirectly ionizing radiation sources (defined only for photon and neutron sources).

Kerma is therefore defined at a point of interest in a volume as the expectation value of the stochastic quantity, energy transferred, to charged particles per unit mass (m) at the point of interest. Kerma can be correlated to the quantities of mass energy transfer coefficient ($\frac{\mu_{tr}}{\rho}$) for photons and Kerma factor (F_n) for neutrons, which are further detailed in (Attix, 2008) and (Veinot, 2019).

The Kerma for X- or γ -rays consists of the energy transferred to electrons and positrons per unit mass of medium. The kinetic energy of fast electrons may be spent in two ways:

- 1) Collision interactions: Coulomb-force interactions with atomic electrons resulting in the local dissipation of the energy as ionization and excitation in or near the electron track.
- 2) Radiative interactions: Coulomb-force interactions with atomic nuclei resulting in the emission of X-ray photons (bremsstrahlung) due to the deceleration of electrons or positron annihilation, that carry energy from the track.

Kerma (K), can be subdivided into two components dependent on whether the energy is dissipated locally through excitations and ionizations, called collisional Kerma (K_c), or whether the energy is carried away by photons, called radiative kerma (K_r):

$$K = K_c + K_r \quad (1)$$

The associated stochastic and deterministic quantities for collisional Kerma and radiative Kerma (K_r being the difference between K and K_c) further described in (Attix, 2008) and (Veinot, 2019).

For monoenergetic photons, K_c is related to the energy fluence (Ψ in MeV cm^{-2}) and mass energy absorption coefficient ($\left(\frac{\mu_{en}}{\rho}\right)_{E,Z}$), which is defined for a given photon energy (E) and the Z of the medium. For neutrons, $K \sim K_c$ because the resulting charged particles from neutron interactions tend to be protons or heavier recoiling nuclei, for which $K_r \sim 0$.

Charged particle equilibrium

Charged particle equilibrium (CPE) is the condition under which each charged particle of a given type, energy, and direction entering a volume is replaced by an identical particle exiting the volume (Attix, 2008; ICRP, 2010). Under CPE conditions at a point in a medium, absorbed dose is equal to collisional Kerma ($K_C =^{CPE} D$), which equates the measurable quantity of absorbed dose with the calculable quantity of collisional Kerma, which is true irrespective of radiative losses.

Transient charged particle equilibrium (TCPE) is said to exist at all points in a region in which $K_C \propto^{TCPE} D$, with a constant of proportionality > 1 . Fig. 4 demonstrates a case where $K_r \approx 0$ (i.e., a case for incident neutrons or for photons up to 3 MeV in a low- Z medium where $K_r < 1\%$ of K) (Maqbool, 2017). The absorbed dose increases with depth near the surface as the number of charged particles flowing into the medium are augmented by increased interactions of indirectly ionizing radiation. The absorbed dose curve reaches a maximum at a depth where the buildup of charged particles is counterbalanced by the descending slope due to attenuation of the indirectly ionizing radiation. Beyond this depth, the absorbed dose curve becomes parallel to the $K = K_C$ curve, where the secondary charged particles starting at the surface penetrate in the direction of the incident rays.

Exposure

Exposure is one of the oldest fundamental quantities in health physics and was introduced before the concepts of Kerma and dose. The units of Röntgen were defined by the ICRU originally in 1928 and are applicable for only X-ray and γ -ray sources. The definition of exposure (X) is the quotient of the absolute value of the total charge (Q) of ions of one sign produced in air when all the electrons (negatron and positron) liberated by photons in air of a given mass (m) are completely stopped in air (ICRU, 2011).

Fig. 4 The relationship between Kerma and absorbed doses for photons and fast neutrons as a function of depth in an absorbing medium under TCPE conditions. Reproduced with permission from Maqbool M (2017) *An Introduction to Medical Physics*. Springer.

Any ionization from bremsstrahlung radiated from the emitted electrons is not included in Q , nor are radiative losses due to positron annihilation. In essence, exposure is the ionization equivalent of K_C for X-ray and γ -ray sources.

To further define exposure, we must introduce the quantity of $\bar{W}$, the mean energy expended in a gas per ion pair formed. This quantity is independent of the incident photon energy. For dry air, $\bar{W}$ is:

$$\bar{W}_{air} = \frac{33.97 \text{ eV/ion pair}}{1.602 \times 10^{-19} \text{ C/electron}} \times \frac{1.602 \times 10^{-19} \text{ J}}{\text{eV}} = 33.97 \text{ J/C} \quad (2)$$

The exposure at a point due to the energy fluence (Ψ) of a monoenergetic photon radiation field of energy, E , can be defined as (Attix, 2008):

$$X = \Psi \left(\frac{\mu_{en}}{\rho} \right)_{E,Z} \left(\frac{e}{\bar{W}_{air}} \right) = (K_C)_{air} \left(\frac{e}{\bar{W}_{air}} \right) = (K_C)_{air} \left(\frac{1}{33.97} \right) \quad (3)$$

where X is given in units in C/kg. To convert from C/kg to units of Röntgen, $1 \text{ R} = 2.580 \times 10^{-4} \text{ C/kg}$.

Therefore, for a given photon energy fluence, the $(K_C)_{muscle}$ per unit exposure is nearly independent of photon energy, with a ratio of $(K_C)_{muscle}/(K_C)_{air} \sim 1.07$ (constant within $\sim 3\%$) for photons between 3 keV and 10 MeV (Fig. 5). This makes it possible to characterize an X-ray field regardless of whether air is located at that point, implying that a photon energy fluence at that point would produce an exposure compared to the energy fluence in Kerma or collisional Kerma for a medium (not necessarily air). This also provides a good approximation to tissue dose using simple measurement of photons.

Furthermore, under CPE conditions, it is possible to equate exposure in air with the absorbed dose:

$$D_{air} \quad (K_C)_{air} = X \left(\frac{\bar{W}_{air}}{e} \right) \quad (4)$$

Protection quantities

Protection quantities are used to establish dose limits for both occupational workers and members of the public from activities involving exposure to radiation. Protection quantities have been derived by ICRP using computational reference anthropomorphic phantoms. Protection quantities have been defined according to recommendations by ICRP, in milestone publications in Publication 26, 60, and 103 (ICRP, 1977b, 1991, 2007). Quantities fundamental to protection are:

- Absorbed dose (described in “Absorbed dose” section);
- Equivalent dose (described in “Equivalent dose and effective dose” section);
- Effective dose (described in “Equivalent dose and effective dose” section)

Equivalent dose and effective dose

Dose limits and administrative controls for delayed stochastic effects are expressed by the quantity, effective dose (E). The latest methodology recommended in ICRP Publication 103 (ICRP, 2007) for the computation of effective dose and its constituent quantities, is captured in Fig. 6.

Fig. 5 Ratio of mass energy absorption coefficients for $X = \text{muscle}$ and $X = \text{water}$ relative to air. Generated using data from (Hubbell and Seltzer, 1995).

Fig. 6 Methodology for the computation of equivalent and effective dose recommended by ICRP Publication 103. Reproduced from ICRP (2007) ICRP publication 103: Recommendations of the international commission on radiological protection. *Annals of the ICRP* 37: 1–332.

In Fig. 6, the application of a radiation-weighting factor, (w_R) represents the biological effectiveness of different radiations to define the quantity of equivalent dose (H_T) in an organ or tissue (T). The units of the derived quantity, equivalent dose, are fundamentally J/kg with the special name, sievert (Sv). The application of a tissue-weighting factor, (w_T) to the equivalent dose, is the same for all types radiations (e.g., alpha, proton, electron, gamma), but different for each organ based on its associated radiosensitivity risk as evaluated by the ICRP. As tissue weighting factors represent relative radiation detriment based on radiosensitivity of organs and tissues, effective dose is proportional to the radiobiological detriment. The sum of the products of H_T and w_T yield the derived quantity of effective dose, (E), which is used to quantify the radiation dose received by an exposed person in units of J/kg with the special name, sievert (Sv) (ICRP, 2007).

The term of effective dose was introduced in ICRP Publication 60 with recommended set of organs to be used in its computation (ICRP, 1991). In addition, the radiation quality factor was further redefined as the radiation-weighting factor, based on the radiation type and energy incident on the body.

As reinforced in ICRP Publication 103 (ICRP, 2007), the radiation-weighted absorbed dose in the organ or tissue is referred to as the equivalent dose, H_T and is calculated via:

$$H_T = \sum_R w_R D_{T,R} \quad (5)$$

where $D_{T,R}$ is the absorbed dose averaged over the organ or tissue (T) from radiation (R).

The computation of effective dose is the sum of the product of the tissue-weighting factor (w_T) (discussed next in “**Tissue-weighting factor**” section) with the sex-averaged value of the equivalent dose (H_T)

$$E = \sum_T w_T \left[\frac{H_T^M + H_T^F}{2} \right] \quad (6)$$

where H_T^M and H_T^F are the equivalent doses to organ or tissue (T) in the male and female models, respectively.

Radiation quality

Quality factor

The Quality Factor, Q , is a dimensionless variable weighting factor to be applied to the absorbed dose to provide an estimate of the relative human hazard of different types and energies of ionizing radiations. The relative biological sensitivity is defined using a quality factor function $Q(L)$ for a charged particle to be the unrestricted linear energy transfer LET [$L = L_\infty$], which is a smooth function and is equivalent to stopping power in water. As a basis of comparison, photons (X-rays and γ -rays) are used as reference radiation to which other radiations are compared. In ICRP Publication 60 (ICRP, 1991), revised from ICRP Publication 21 (ICRP, 1977a), reflects the $Q(L)$ - L relationship given in Table 1. LET is the integral of stopping power to a cutoff energy that is characteristic of the local distance of ionization of the charged particle.

Radiation weighting (w_R)

The recommendations made by ICRP for biological effectiveness associated with the type of incident radiation have evolved based on the latest available scientific data from recommendations in Publication 60 to current recommendations in ICRP Publication 103. Both Recommendations for w_R from ICRP Publication 60 (ICRP, 1991) and ICRP Publication 103 (ICRP, 2007) are tabulated in Table 2.

The continuous function representing the neutron w_R was developed to serve as an approximation as a function of neutron energy (E) in MeV. ICRP Publication 60 defines this function as (ICRP, 1991):

$$w_R = 5 + 17e^{-\frac{(\ln(2E))^2}{6}} \quad (7)$$

The continuous function representing the neutron w_R was developed to serve as an approximation as a function of neutron energy (E) in MeV. ICRP Publication 103 defines this function as (ICRP, 2007):

$$w_R = \begin{cases} 2.5 + 18.2e^{-\frac{(\ln(E_n))^2}{6}} & E_n < 1 \text{ MeV} \\ 5 + 17.0e^{-\frac{(\ln(2E_n))^2}{6}} & 1 \text{ MeV} \leq E_n \leq 50 \text{ MeV} \\ 2.5 + 3.25e^{-\frac{(\ln(0.04E_n))^2}{6}} & E_n > 50 \text{ MeV} \end{cases} \quad (8)$$

A comparison of the neutron radiation weighting factors are plot in Fig. 7.

Table 1 ICRP Publication 60 Quality Factor $Q(L)$ as function of L from ICRP Publication 21 (ICRP, 1977a) and Publication 60 (ICRP, 1991).

L ($\text{keV } \mu\text{m}^{-1}$)	ICRP Publication 21 $Q(L)$	L ($\text{keV } \mu\text{m}^{-1}$)	ICRP Publication 60 $Q(L)$
≤ 3.5	1	< 10	1
7	2	10–100	$0.32L - 2.2$
23	5	> 100	$300/\sqrt{L}$
53	10		
≥ 175	20

Fig. 7 Neutron radiation weighting factors given in ICRP Publication 60 (ICRP, 1991) and ICRP Publication 103. Reproduced using data from ICRP (2007) ICRP publication 103: Recommendations of the international commission on radiological protection. *Annals of the ICRP* 37: 1–332.

Tissue-weighting factor

The recommendations made by ICRP for radiation risk and detriment associated with constituent tissues and organs of the human body have also evolved with the latest scientific recommendations. The recommendations for tissue-weighting factors (w_T), which are independent of incident radiation type, are provided per the recommendations of ICRP Publication 26, ICRP Publication 60, and ICRP Publication 103 (ICRP, 1977b), ICRP Publication 60 (ICRP, 1991) and ICRP Publication 103 (ICRP, 2007) in Table 3.

Operational quantities

Protection quantities define dose limits to populations of members of the public and occupational workers through the establishment of organ absorbed dose, equivalent dose, and effective quantities. However, these protection quantities cannot be applied to calibration or radiation detection instrumentation. Consequently, operational quantities were developed by the ICRU to correlate measurable quantities with calculated protection quantities. Operational quantities have been developed by ICRU in Report 39 (ICRU, 1985), Report 43 (ICRU, 1988), Report 47 (ICRU, 1992), Report 51 (ICRU, 1993), Report 60 (ICRU, 1998b), and Report 85a (ICRU, 2011). Where protection quantities employ the (w_R) in tissue, operational quantities employ (Q), to differentiate biological effectiveness of radiation.

Operational quantities are used to correlate the protection of effective dose and operational-derived quantities for recommendations of whole body dose, dose to lens of the eye, and dose to skin. The operational quantities applied to area monitoring are ambient dose equivalent and directional dose equivalent; for individual monitoring, the operational quantity of personal dose equivalent is defined.

Table 3 Comparison of tissue-weighting factors per ICRP from ICRP Publication 26 (ICRP, 1977b), ICRP Publication 60 (ICRP, 1991) and ICRP Publication 103 (ICRP, 2007).

Tissue/organ ^a	ICRP publication 26 ^b	ICRP publication 60 ^c	ICRP publication 103 ^d
Gonads	0.25	0.20	0.08
Bone marrow (red)	0.12	0.12	0.12
Colon		0.12	0.12
Lungs	0.12	0.12	0.12
Stomach		0.12	0.12
Bladder		0.05	0.04
Breast	0.15	0.05	0.12
Liver		0.05	0.04
Esophagus		0.05	0.04
Thyroid	0.03	0.05	0.04
Skin		0.01	0.01
Bone surface	0.03	0.01	0.01
Remainder	0.32	0.05 ^c	0.12 ^d
Brain			0.01
Salivary glands			0.01

^aOrgans without tissue-weighting factors defined comprise the remainder.

^bThe five most highly irradiated other organs and tissues.

^cAdrenals, brain, upper large intestine, small intestine, kidneys, muscle, pancreas, spleen, thymus, and uterus (female).

^dAdrenals, extrathoracic tissue, gall bladder, heart, kidneys, lymphatic nodes, muscle, oral mucosa, pancreas, prostate (male), small intestine, spleen, thymus, uterus/cervix (female).

For all types of external radiation, the operational quantities for area monitoring are defined on the basis of a dose-equivalent quantity that would exist in the ICRU sphere (30 cm in diameter) as a theoretical construct of tissue-equivalent material of ICRU four-element tissue with a density of 1 g/cm³, and a composition of 76.2% oxygen, 11.1% carbon, 10.1% hydrogen, and 2.6% nitrogen (ICRP, 2010). The radial depths (*d*), depicted in Fig. 8 (Shannon, 2009), of the sphere correspond to control levels for the whole body dose, lens of the eye doses, and skin dose (Table 4). One key limitation of the ICRU sphere is that it is composed of a material that cannot be manufactured, but can only be simulated.

Fig. 8 Schematic of ICRU sphere employed in ambient dose equivalent calculations. Reproduced from Shannon MP (2009) *The Dosimetry of a Highly-Collimated Bremsstrahlung Source in Air*. Doctor of Philosophy. Georgia Institute of Technology.

Table 4 Scheme of operational quantities used for dose monitoring in external exposure situations.

Task	Area monitoring	Personnel monitoring
Control of effective dose	Ambient dose equivalent $H^*(10)$	Personal dose equivalent $H_p(10)$
Control of dose to the lens of the eye	Directional dose equivalent $H'(3, \Omega)$	Personal dose equivalent $H_p(3)$
Control of dose to skin, hands, and feet	Directional dose equivalent $H'(0.07, \Omega)$	Personal dose equivalent $H_p(0.07)$

Reproduced from ICRP (2010) ICRP publication 116: Conversion coefficients for radiological protection quantities for external radiation exposures. *Annals of the ICRP* 40: 1–257.

Area monitoring

Ambient dose equivalent

The ambient dose equivalent, $H^*(d)$, at a point in a radiation field is the dose equivalent that would be produced by the corresponding expanded and aligned field in the ICRU sphere at a depth, d , on the radius opposing the direction of the aligned field (ICRU, 2011). As explained in ICRP Publication 74 (ICRP, 1997), an expanded and aligned radiation field is a hypothetical field where the fluence and its energy distribution are the same as an expanded field, but the fluence is unidirectional. Corresponding to effective dose, the ambient dose equivalent is the dose equivalent that would be produced in a corresponding radiation field in the ICRU sphere at a depth of 10 mm. Therefore, the recommended value of d in the ICRU sphere is 10 mm with notation $H^*(10)$ (ICRP, 1997). The units of ambient dose equivalent are (J/kg) as Sv.

Directional dose equivalent

The directional dose equivalent, $H'(d, \Omega)$, is used for assessing the dose to the skin, extremities (hands, wrists, and feet), and lens of the eye. The directional dose equivalent at a point in a radiation field is the dose equivalent that would be produced by the corresponding expanded field in the ICRU sphere at a depth, d , on a radius in a specified direction, Ω . For assessing dose to skin and the extremities, a depth of $d = 0.07$ mm is recommended, with notation, $H'(0.07, \Omega)$. For monitoring dose to the lens of the eye, depth $d = 3$ mm, with notation, $H'(3, \Omega)$. The quality factor is employed to assess radiation quality as a function of LET.

Personnel monitoring

Personal dose equivalent

When calibrating the dosimeters of occupational workers, the corresponding operational quantity of interest is the personal dose equivalent, $H_p(d)$, at a depth, d , in units of J/kg as Sv. Similar to the parameters defined in area monitoring in ambient and directional dose equivalent, the same depths are recommended for personal dose equivalent, which are: 10 mm for penetrating radiation, 3 mm for lens of the eye, and 0.07 mm for skin (ICRP, 2010).

In computing personal dose equivalent for dosimeter calibration, the ICRU specifies a 30 cm × 30 cm × 15 cm-thick slab phantom representing the trunk of the body, and constructed of the 4-element ICRU tissue. This measurement is denoted by the corresponding quantity as $H_{p, \text{slab}}(d)$. Since ICRU tissue cannot be fabricated, calibrations frequently use polymethyl methacrylate (PMMA) with thermoluminescent detectors.

Table 4 summarizes the application of the different operational dose quantities with protection values.

Early radiation protection efforts

After noticing severe health problems caused by radioactivity, the original dose limit of approximately 10 rad per day (or 3000 rad per year, where 1 rad = 0.01 Gy), was suggested in 1902. The 10 rad-per-day (0.1 Gy) limits were not based on evaluated biological data but rather on the lowest amount that could be surely detected, particularly, the amount required to create a visible exposure or fogging, on a photographic plate. Animal studies in 1903 had shown that X-rays could produce cancer and kill living tissues. The organs most exposed to radiation injury were the skin, the blood-forming organs, and the reproductive organs (Inkret et al., 1995). Table 5 includes measures of dose rates found by radiation workers in the early part of the 20th century:

By 1905, there was a general acceptance that X-rays could indeed be harmful, and radiation protection was introduced (Kang, 2016). The earlier typical opinion had changed, and the general belief now among physicians, scientists, and those working with X-rays, as well as the general public, was that X-rays were indeed the cause of the harmful effects. Precautions were needed to ensure their safe use in medicine. The change was mostly attributable to a better knowledge of the scientific aspects, particularly physics of X-rays and radioactivity. It was also due to the growing body of publications in the medical and scientific literature describing contrary effects of exposure to X-rays, including deaths among some of the early workers. There had also been higher sophistication and less tolerance in public attitudes regarding potential hazards. The first of these X-ray victims was Clarence Dally, Thomas Edison's assistant, who had suffered significant exposures in 1896 and who subsequently died in 1904.

Table 5 Dose rates for radiation workers in the early part of the 20th Century.

Occupation	Approximate dose rate (rad min^{-1}) ^a
Fluoroscopist	0.6–6 (hands)
X-ray therapy technician	0.006–0.06 (body)
Radium therapist or technician	0.006–0.06 (body)

^a1 rad is defined as 0.01 Gy.

Adopted from Inkret WC, Meinhold CB and Taschner JC (1995) Protection standards. *Los Alamos Science* 23: 117–123.

Along with recognizing the problem came several suggested resources made by some well-known protection pioneers. Although they did not have sufficient knowledge of the nature of X-rays, they helped to minimize the adverse effects. Nevertheless, more information concerning the physical nature of the X-rays was required including a practical, globally accepted means of quantification, specified limitations on exposure, advancements in devices, procedure, and processes. Most of the progress came from the medical applications, for this was where most problems were seen (Kathren, 2019).

William Herbert Rollins had made recommendations for examining X-ray areas by using film in 1902. He suggested that if a photographic plate was not fogged in 7 min, then the radiation field was not dangerous. Rollins, a dentist from the Boston area, should be considered a leading pioneer in the radiation protection field. The basic principles for developing X-ray protection techniques existed early in the gas tube period. Meanwhile, more and more evidence of X-rays' ability to produce cancer continued to be collected. However, between 1900 and 1913, little effort was made toward developing radiation protection systems (McGinley and Miner, 1995).

Early cohort studies

By 1910, many people who used X-ray generating and radioactive material began to develop skin inflammations, which eventually led to early skin cancer. Therefore, scientists presumed that exposure to radiation could cause infertility, bone disease, and cancer. During the early years, there were no regulated systems for the measurement of radiation exposure or the estimation of radiation dose. However, some work had been done to standardize and formalizing the quantities and units related to radioactivity. In 1925, an investigation carried by Harrison S. Martland, a New Jersey Medical inspector, suggesting that evidence related to radium intake by female factory workers could lead to serious illness and fatality (Jones, 2005).

In 1920 radioluminescent paints, made by combining radium with fluorescent materials, were popular in the production of watch and clock dials, gun sights, and other applications. Many firms, including the Radium Luminous Material Corporation (reorganized as a successor company, United States Radium Corporation) purchased the paint, which was applied, almost exclusively by women referred to as the "Radium Girls," to the clock dials with tiny brushes. One company reported that about 4300 dials were painted every day (Turner, 2008). The workers ingested a large amount of radium, a bone-seeking element, by repeatedly sharpening the tip of the brush with their lips. By the 1920s, numerous cases of radiation-related diseases and fatalities were reported in the radium related industries. More than 1000 individuals had the amount of radium in their bodies measured. Bone samples were gathered after death and examined. An official guide of 0.1 μg for the maximum allowable amount of ^{226}Ra in the body was later established. Legal action was against the U.S. Radium Corporation by employees experiencing radiation poisoning (Fig. 9).

It was estimated that this level corresponds to an average dose rate of 0.6 mGy week^{-1} and a dose equivalent rate of somewhere between ~ 1 and $\sim 6 \text{ mSv week}^{-1}$ (Turner, 2008). The large majority of the "Radium Girls" received no compensation from the company. The U.S. Radium Corporation was reorganized into new corporations and ultimately dissolved following 1980. The former radium processing facilities, which included the dial painting studio of Orange, New Jersey, became a U.S. Environmental Protection Agency Superfund cleanup site (Dabbs, 2018).

Uranium miners' experience is another significant source of information on the negative consequences of radiation. These data are particularly relevant to exposure to the daughters of radon everywhere. From the early days of the Medieval period, it was noticed that miners in some regions of Europe had abnormally high numbers of lung diseases, also known as mountain sickness. During the 20th century, miners worked in an environment with high concentrations of dust, containing elements such as arsenic, uranium, and other alloys. The rate of lung cancer was raised among the workers, and consequently, half of the workers died of this disease. It took scientists a while to realize that the radon and its daughters were the leading cause of this disease.

The reports of many miners throughout the world have been studied and investigated by the Biological Effects of Ionizing Radiation (BEIR) VI report, *Health Effects of Exposure to Radon* (National Research Council, 1999), updating the 1988 BEIR IV report (National Research Council, 1988). Further, models have been generated to estimate the exposure of the radon daughters to lung tissues per working level month (WLM). The value of absorbed doses is somewhere between 0.2 and 3.0 mGy. The result of a group of 11 studies that involved 60,606 highly exposed workers from all over the world, shows that the average exposure was 164.4 WLM, and the average time, 5.7 years. There were about 2000 lung-cancer deaths reported among the exposed people. To determine the risks at low doses; the data were compared with other studies that had smaller mean exposures (Turner, 2008).

Another study that was performed on underground miners in New Mexico showed the same results, such as lung cancer and disease due to radon and its decay products. This study also proved that uranium dust has little to no effect on an individual's health, which is

Fig. 9 Letter of complaint to U.S. Radium Corporation documenting radiation poisoning of five workers (National Archives, 1929).

because uranium ore is not very radioactive and gamma radiation from uranium dust is low. Underground miners were exposed to radon, causing serious health problems for them. However, uranium millers were exposed to uranium dust, and no sign of cancer or other diseases were observed. The result of this study proved that unlike radon, uranium dust does not pose a major health hazard (Boice et al., 2008).

Table 6 Major milestones in the discovery of radiation.

Year	Event
1895	Roentgen discovers ionizing radiation
1896	Elihu Thomson experiment, reveals the harmful effect of X-ray
1896	Henri Becquerel discovers alpha and beta particles
1898	Curie discovers and isolates polonium and radium which later caused cancer
1900	American Roentgen Ray Society (ARRS) founded
1902	Ernest Rutherford discovers isotopes
1902	Dose limit of approximately 10 rad per day (or 3000 rad per year), was suggested
1902	Rollins had made recommendations for examining x-ray areas by using film
1903	Animal studies in had shown that X-rays could produce cancer and kill living tissues
1905	Link that radiation can cause cancer
1915	British Roentgen Society adopts X-ray protection resolution; believed to be the first organized step toward radiation protection
1932	James Chadwick discovered the neutron
1932	Cockcroft and Walton produced nuclear transformations by bombarding atoms with accelerated protons
1935	Enrico Fermi found that a much greater variety of artificial radionuclides could be formed when neutrons were used instead of protons
1939	Hahn and Strassman discover Nuclear fission, induced by capture of a slow neutron in ^{235}U
1939	Bohr soon proposed that fission was much more likely to occur in the uranium-235 isotope than in U-238 and that fission would occur more effectively with slow-moving neutrons than with fast neutrons
1939	Szilard and Fermi propose using a “moderator” to slow down the emitted neutrons
1939	WWII begins
1942	An experimental graphite pile constructed by Fermi operated at the University of Chicago established the first man-made fission chain reaction
1945	The first atomic device tested successfully at Alamogordo, New Mexico; detonation of atomic bombs in Hiroshima and Nagasaki, Japan, marking the end of WWII
1953	President Eisenhower proposed his “Atoms for Peace” program, which set the course for civil nuclear energy development in the United States
1979	Three Mile Island reactor accident
1986	Disaster at the Chernobyl nuclear power plant
2011	Earthquake and tsunami prompting Fukushima Daiichi Nuclear Power Plant incident

Milestones in the discovery of radiation and its effects

Table 6 lists a timeline of key milestones in the discovery of radiation, the early evolution of radiation protection practices, and a few notable events.

The future of radiation protection

Management and limitation of radiation exposure has led to the growth of field of health physics, where a broad spectrum of issues require attention and must eventually be addressed to ensure that radiation protection programs in the energy, industrial, medicine, defense, and security sectors continue to meet these emerging needs. Efforts must be focused conducting focused research in critical scientific/mission areas and advancing training and developing of skilled radiation personnel. Recently, a series of future priorities has been established in health physics and radiation protection in the fields of nuclear energy, medicine, dosimetry/risk, space travel, instrumentation/operations, environment, decontamination/decommissioning, emergency response, defense, and effects from exposures to low dose radiation (Dewji et al., 2017; Davis et al., 2019). As these fields continue to study the utility of radiation sciences and technology, radiation protection will continue to evolve in tandem to limit and control radiation exposure.

Interactions of radiation with matter—including tissue, shielding materials, and radiation detectors—all stem from fundamental physical interactions at the atomic and sub-atomic level of interest in health physics and radiation protection.

Nuclear physics

The structure of the atom

Prior to the postulate of the “Standard Model of Fundamental Particles and Interactions” in 1968, neutrons and protons were generally considered to be fundamental particles. However, results from studies of high energy particles made it clear that the structure of the nucleus was composed of more components than only neutrons and protons. As a result, the “Standard Model” was developed.

In the “Standard Model”, there are 12 fundamental matter particle types (quarks and leptons) and their corresponding antiparticles. Quarks have charges of either $+2/3$ or $-1/3$, and they are held together with force-carrying particles in combinations of three to form particles with charges of $+1$, -1 , and neutral. The force-carrying particles include the following: photon, gluon, Z boson, and W boson. It is interesting to note that the top quark was not discovered until 1995 by Fermilab ([Abe et al., 1995](#)) and that a Higgs boson was not discovered until 2012 ([Aad et al., 2012](#); [Chatrchyan et al., 2012](#)). The Higgs boson is sometimes called the “God particle” since the theory associated with the Standard Model implies that it gives mass to all other particles and that a universe-wide Higgs field exists.

There are three general families of matter, as shown in [Fig. 1](#) ([Ling et al., 2019](#)), but most health physics, radiation protection, and nuclear engineering disciplines are concerned with the first family that include up quark, down quark, electron neutrino, and the electron, which associate to form photons, electrons, positrons, protons, and neutrons. Neutrinos and anti-neutrinos are generally included in discussions of beta decay (see section [Beta decay](#)).

Proton

Protons presumably exist in the nucleus of an atom and govern the identity and chemical properties of the atom. The atomic number, Z , is the number of protons in the atom, and define the elemental properties of the atom. Protons are comprised of two up quarks (each with unit charge $+2/3$) and one down quark (unit charge $-1/3$) resulting in a total net charge of $+1$ for the proton, or 1.602×10^{-19} Coulombs (C) per unit charge. The rest mass of the proton is 1.673×10^{-27} kg (Baum et al., 2002) with the mass-energy equivalent rest mass of 938.272 MeV/c².

Neutron

Neutrons are also presumed to exist in the nucleus of an atom and are comprised of one up quark (+2/3 charge) and two down quarks (-1/3 charge each) resulting in a net neutral charge. The rest mass of the neutron is slightly larger than a proton at 1.675×10^{-27} kg (Baum et al., 2002) and a rest mass of 939.566 MeV/c².

Electrons

Electrons are fundamental particles, known as leptons, that exist outside of the nucleus of the atom and govern the chemical interactions of the atom, as well as some nuclear interactions. They have a net charge of -1 and mass of 9.11×10^{-31} kg and rest mass of 0.511 MeV/ c^2 . Neutral atoms have an equal number of protons (Z) and electrons. Electrons occupy the region outside of the nucleus in shells. The discrete energy states occupied by electrons are dictated by quantum mechanical probabilities, in which electrons can excite and de-excite between energy states.

Fig. 1 Families of Matter: Leptons, quarks, and force carriers. Radiation protection and related disciplines focus on: up/down quarks that constitute protons and neutrons; electron neutrinos/anti-neutrinos and electrons/positrons leptons; and photon force carriers. Reproduced from Ling SJ, Sanny J and Moebs W (2019) *University Physics Volume 3*. OpenStax CNX. Available: <http://cnx.org/contents/af275420-6050-4707-995c-57b9cc13c358@12.2> (Accessed 2020).

Nucleus

Together the sum of the atomic number and the number of neutrons (N) is mass number ($Z + N = A$), which represents the integer number of nucleons in the nucleus of an atom. A radionuclide is symbolically represented by A_ZX , where X represents the element. For example, ${}^{12}_6\text{C}$ represents the carbon nucleus with six protons and six neutrons (totaling 12 nucleons). ${}^{17}_8\text{O}$ represents the oxygen nucleus with eight protons and nine neutrons (totaling 17 nucleons).

Isotopes, isotones, and isobars

Elements with different number of neutrons (and hence nucleons) are called isotopes. Certain isotopes are unstable and may undergo nuclear transformations by emitting energetic particles, converting neutrons into protons, converting protons into neutrons, or de-excitation through the emission of photons to reach a more stable energetic state. These will be discussed in further detail in the section, **Radioactive Decay**.

Elements with the same number of neutrons (though not the same number of protons) are referred to as isotones, and those with the same number of nucleons are referred to as isobars.

Atomic mass unit

The atomic mass is the mass of the atom inclusive of the bound protons, neutrons and electrons. If one mole of any material contains 6.022×10^{23} atoms (Avogadro's number), and the weight of one mole is defined by the atomic mass unit, then the weight of a single atom can be calculated. For example, 1 mol of ${}^{12}_6\text{C}$ has a unique mass of 12.0000 g, which results in the mass of a single atom of ${}^{12}_6\text{C}$ as:

$$\frac{12.0000 \text{ g} \cdot \text{mol}^{-1}}{6.022 \times 10^{23} \text{ atoms} \cdot \text{mol}^{-1}} = 1.993 \times 10^{-23} \text{ g} \quad (1)$$

Since the atomic mass of ${}^{12}_6\text{C}$ is a whole, round number, carbon was selected as the reference value for the system of relative masses. The mass of an atom can be given in grams or in a relative quantity called the atomic mass unit (amu), where,

$$1 \text{ amu} = \frac{1.993 \times 10^{-23} \text{ g}}{12} = 1.661 \times 10^{-24} \text{ g} = 1.661 \times 10^{-27} \text{ kg} \quad (2)$$

In mass-energy equivalent units using Albert Einstein's $E = mc^2$ relation, where c = speed of light in a vacuum ($3 \times 10^8 \text{ m/s}$)

$$E(1 \text{ amu}) = \frac{(1.661 \times 10^{-27} \text{ kg} \cdot \text{amu}^{-1})(3 \times 10^8 \text{ m} \cdot \text{s}^{-1})^2}{1.6 \times 10^{-13} \text{ J} \cdot \text{MeV}^{-1}} = 931.5 \text{ MeV} \quad (3)$$

We can define a "mass excess," Δ , as the difference between the atomic mass and mass number ($M-A$) in amu or MeV equivalent. Masses of radionuclides can be defined relative to ${}^{12}_6\text{C}$, in which Δ for ${}^{12}_6\text{C}$ is 0. A compendium of mass excess value for a series of radionuclides are given in [Turner \(2008\)](#) and [Wang et al. \(2017\)](#).

Binding energy

If it was possible to weigh an individual atom, it would be found that the atom weighs less than its constituent parts, inclusive of all its protons, neutrons, and electrons. For example, if the sum of the constituent protons and neutrons of an atom is computed, this yields ([Cember et al., 2008](#)):

$$W = (Z)m_p + (A - Z)m_n \quad (4)$$

where W = mass of sum of constituent nucleons; m_p = proton mass = 1.00728 amu; m_n = neutron mass = 1.00867 amu; Z = atomic number; A = mass number.

For the example of ${}^{17}_8\text{O}$, with $Z = 8$ and $A = 17$:

$$W = (8)(1.00728 \text{ amu}) + (17 - 8)(1.00867 \text{ amu}) = 17.1363 \text{ amu} \quad (5)$$

However, the mass of ${}^{17}_8\text{O}$ atom is $A = 16.9991$ amu. The missing mass is equivalent to the energy binding the nucleus together, which is equal to $(17.1363 - 16.9991) = 0.13717$ amu. This behavior is true not just for the example of ${}^{17}_8\text{O}$, but also for all radionuclides. This difference between the atomic mass of an element A_ZX and W is referred to as the mass defect, δ (in amu), where

$$\delta = W - M_X(A, Z) \quad (6)$$

Therefore, the mass defect is the mass equivalent of the energy that must be expended to separate the nucleus into its individual constituent nucleons, called the binding energy (BE), such that they are separated by a distance large enough so they exert no forces on each other. Conversely, the BE can also be interpreted as amount of energy released if free nucleons were to coalesce into a nucleus ([Fig. 2](#)).

Fig. 2 The binding energy (BE) is the energy required separate all nucleons into its constituent protons and neutrons. The sum of the constituent nucleons is larger than the bound nucleons. Reproduced from Ling SJ, Sanny J and Moebs W (2019) *University Physics Volume 3*. OpenStax CNX. Available: <http://cnx.org/contents/af275420-6050-4707-995c-57b9cc13c358@12.2> (Accessed 2020).

The BE is therefore defined as the energy required to remove a subatomic particle from an atom:

$$BE = \delta \text{ (amu)} \times \frac{931.5 \text{ MeV}}{\text{amu}} \quad (7)$$

An important quantity in experimental nuclear physics is the binding energy per nucleon (BEN), which is defined as:

$$BEN = \frac{BE}{A} \quad (8)$$

BEN values are measured from nuclear scattering experiments. A graph of the BEN as a function of atomic number A is shown in **Fig. 3**. In this graph, the BEN typically ranges from ~ 7 – 9 MeV, with a broad maximum ~ 8.5 MeV/nucleon. It takes millions of electron volts to separate a nucleon from the nucleus, demonstrating that the nuclear force binding the nucleons is indeed strong, giving rise to the specific binding force in the nucleus called the “strong nuclear force.” The highest BEN falls around ${}^{62}_{28}\text{Ni}$ at 8.795 MeV/nucleon, followed by ${}^{58}_{26}\text{Fe}$ and ${}^{56}_{26}\text{Fe}$ at 8.792 MeV/nucleon and 8.790 MeV/nucleon (Veinot, 2019).

An interesting implication of this curve is that elements to the left of the most stable region must undergo fusion of light elements to undergo an exothermic reaction (i.e., release energy), whereas elements to the right must undergo fission of heavy elements to undergo an exothermic reaction. These two interactions will be discussed later in (see section **Neutrons**).

Fig. 3 Binding energy per nucleon (BEN) plot as a function of mass number. The greatest BEN falls around ${}^{56}_{26}\text{Fe}$, making radionuclides in this region the most stable nuclei. Reproduced from Ling SJ, Sanny J and Moebs W (2019) *University Physics Volume 3*. OpenStax CNX. Available: <http://cnx.org/contents/af275420-6050-4707-995c-57b9cc13c358@12.2> (Accessed 2020).

Electromagnetic spectrum

Photons and electrons (as well as any elementary particle) may manifest as particles or waves, depending on how they are observed. For example, if electrons are directed towards a target with a double slit, a wave pattern will emerge. On the other hand, if the electrons are observed with a counting system, they behave as particles, as demonstrated by Clinton Davisson and Lester Germer in their experiments between 1923 and 1927, where Davisson received the Nobel Prize in Physics in 1937 for “experimental discovery of the diffraction of electrons by crystals” (Davisson and Germer, 1927). Low energy photons, at radio frequency, manifest as waves while high energy photons manifest as particles. In order for neutrons to exhibit wave-like behavior they must be cooled to a few degrees Kelvin. Fig. 4 illustrates the utility and the hazards of electromagnetic radiation in society, as well as the relationship between the energy, frequency, and wavelength of electromagnetic radiation according to the equation derived by Max Planck (Planck, 1901) and harnessed by Albert Einstein to explain the photoelectric effect (Einstein, 1905) (see section Photoelectric Effect).

Radiowaves at the left-most side of portion of the spectrum in Fig. 4 have the lowest frequency and the longest wavelength.

- Radio wavelengths vary from ~ 3 m to 100 m.
- Radio waves are also emitted by other sources, such as stars and gases in space.

Microwave radiation falls above the radio spectrum in terms of energy.

- Wavelength is between 1 mm and 30 cm.
- Can be used to study the universe, communicate with satellites in Earth orbit, and cook popcorn.

Infrared (IR) radiation has wavelengths between 700 nm and 1 mm.

- The name means “below red”—red being the color of visible light of longest wavelength.
- Common use of IR is in night vision equipment and television remote controls since it does not penetrate walls and interfere with other devices.
- The heat that we feel from the Sun or from a fireplace is infrared radiation.

Visible Light is electromagnetic radiation at wavelengths which the human eye can see.

- We perceive this radiation as colors ranging from red (longer wavelengths; ~ 700 nm) to violet (shorter wavelengths; ~ 400 nm.)

Ultraviolet radiation is shorter than the violet end of visible light; the atmosphere of the Earth effectively blocks the transmission of most ultraviolet light.

- It is the UV rays that cause our skin to burn! Stars and other “hot” objects in space also emit UV radiation.
- At a wavelength of up to 320 nm, which includes most of the ultraviolet band, these energies can be classified as ionizing radiation.

X-Ray and Gamma ray radiation have the shortest wavelength and therefore the highest frequency at the right-most side of Fig. 4.

- They are also the most energetic part of the spectrum.
- These are classified as ionizing radiation.

Fig. 4 The electromagnetic spectrum as a function of frequency. As the frequency increases, the energy of the wave increases and as the frequency decreases, the energy of the wave decreases. Reproduced from Lawrence Berkeley Laboratory.

Radioactive decay

Radioactivity denotes the property of spontaneous transformation of state in a nucleus that results in the release of energy in the form of electromagnetic waves or particle emissions. These properties of radionuclides are determined by nuclear considerations only, independent of chemical and physical states of the radionuclide, making these properties unique and characteristic of the respective radionuclide. The specific mode of radioactive transformation is dependent on the available energy for the transition, which further depends on (1) the type of nuclear instability (ratio of protons and neutrons); and (2) mass-energy relationships among the radioactive parent, progeny, and emitted particles.

Fig. 5 shows a “band of stability” that represents a region in which stable species exist. Above the band exists an excess of neutrons, and below the band exists an excess of protons. In regions of excess of either protons or neutrons, nuclei will seek to transform these excess particles to drive towards more stable states aligned with the “band of stability.” For radionuclides with an excess of neutrons, the nucleus will undergo transformations towards more stable state by transforming a neutron into a proton and typically decays by emitting an electron. For radionuclides with an excess of protons, compared to neutrons, the nucleus will undergo transformations towards a more stable state by transforming excess protons into neutrons, and typically decays by emitting a positron, the anti-particle of the electron.

Alpha decay

Alpha decay is a process of radioactive decay in which a heavy parent radionuclide with atomic number Z and mass A spontaneously emits an alpha (α) particle (i.e., a He nucleus with $Z = 2$, $A = 4$, and charge $+2$) producing a daughter radionuclide with atomic number $Z-2$ and mass number $A-4$.

$${}^A_ZP \rightarrow {}^{A-4}_{Z-2}D + {}^4_2\alpha + Q \quad (9)$$

Almost all naturally occurring alpha emitters come from heavy elements with $Z > 83$. The range of an alpha particle is very short, $\sim 2\text{--}10$ cm in air. Alpha particles have low penetrating power and can be easily shielded by paper or by the outer layer of the skin. However, if radionuclides undergoing alpha decay are internalized such as through inhalation, ingestion, or skin absorption, then this potentially poses a significant internal health hazard. For example, radon is a noble gas that can diffuse into environmental systems and homes after being formed by the alpha decay of ${}^{226}_{88}\text{Ra}$:

Fig. 5 Plot of number of number of neutrons vs. number of protons for stable atomic nuclei. Stable radionuclides exist along the “band of stability”. Radionuclides above the “band of stability” have an excess of neutrons, whereas those below have an excess of protons. Reproduced from Ling SJ, Sanny J and Moebis W (2019) *University Physics Volume 3*. OpenStax CNX. Available: <http://cnx.org/contents/af275420-6050-4707-995c-57b9cc13c358@12.2> (Accessed 2020).

Radon decays to polonium isotopes that attach to dust particles and subsequently reside in lungs for days, weeks or even years, depending of the solubility class of dust particles. Polonium isotopes decay by alpha emission and are an internal hazard if the polonium particles are inhaled and remain in the lungs. Radon is a noble gas and does not pose a direct health concern compared to its progeny.

In Eq. (10), Q is equal to the total amount of kinetic energy released in radioactive decay, equal to the difference in the total mass of the system. If Q is >0 , the reaction is exothermic, and if $Q < 0$, the reaction is endothermic.

$$Q = M_P - (M_D + M_\alpha) = \Delta_P - (\Delta_D + \Delta_\alpha) \quad (11)$$

where M_P = nuclear mass of parent nuclide; M_D = nuclear mass of daughter nuclide; and M_α = nuclear mass of alpha particle; Δ_P = mass excess of parent nuclide; Δ_D = mass excess of daughter nuclide; and Δ_α = mass excess of alpha particle. The nuclear mass difference is nearly equal to the atomic mass difference, with the exception of the slight difference in the binding energies of the 88 electrons on either side of the arrow, which are neglected when atomic mass loss is equal to nuclear mass loss. In essence, the nuclear masses are needed but atomic masses are much better known, resulting in negligible differences.

To calculate the Q -value of the alpha decay of $^{226}_{88}\text{Ra}$ from Eq. (10) by applying Eq. (11):

$$\begin{aligned} Q &= M_{^{226}_{88}\text{Ra}} - (M_{^{222}_{86}\text{Rn}} + M_{^4_2\alpha}) \\ Q &= 226.025402 - (222.017570 + 4.002603) \text{ amu} \\ &\text{as mass excess : } 23.69 \text{ MeV} - (16.39 \text{ MeV} + 2.4248 \text{ MeV}) \\ Q &= 0.005229 \text{ amu} = 4.87 \text{ MeV} \end{aligned} \quad (12)$$

Alpha decay is an exothermic process, yielding Q -values in the range of 4–9 MeV. The energy released (Q -value) is distributed as kinetic energy between the emitted two particles following decay. If conservation of energy and momentum is applied, the following kinetic energy distribution between the daughter (E_D) and the alpha particle (E_α) can be calculated:

$$E_\alpha = \frac{M_D Q}{M_\alpha + M_D} \quad (13)$$

$$E_D = \frac{M_\alpha Q}{M_\alpha + M_D} \quad (14)$$

In the decay of $^{226}_{88}\text{Ra}$, the kinetic energy of the alpha particle is 4.78 MeV, where the recoil energy of the daughter, $^{222}_{86}\text{Rn}$, is 0.087 MeV. The decay scheme of $^{226}_{88}\text{Ra}$ is given in Fig. 6. Note that 94.4% of $^{226}_{88}\text{Ra}$ transformations decay directly to $^{222}_{86}\text{Rn}$ with an associated alpha particle energy of ~ 4.78 MeV, and 5.5% to an excited metastable state $^{226}_{88}\text{Ra}$ with an alpha energy of 4.60 MeV, accompanied by the emission of a characteristic gamma-ray of 0.186 MeV (gamma emissions will be discussed further in section Gamma emission).

Beta decay

Beta (β) decay is type of radioactive decay in which the nucleus is transformed without changing the number of nucleons. These transitions, called isobaric transitions, include the processes of β^- , β^+ , and electron capture (EC).

β^- Decay

β^- decay occurs in low- Z nuclei that are neutron rich. These neutron rich nuclei gain stability by decreasing the N/Z ratio by converting a neutron to a proton. In β^- decay, an antineutrino and a negative electron are emitted from the nucleus as a result of the

Fig. 6 Alpha decay scheme of $^{226}_{88}\text{Ra}$. Reproduced from Turner JE (2008) Atoms, Radiation, and Radiation Protection. John Wiley & Sons.

transformation of a neutron into a proton, where A remains the same. A general example for the decay of a parent (P) to a daughter (D), an electron (${}^0_{-1}e$), and antineutrino where an energy of Q is imparted to the daughter and beta particle:

In summary,

where an electron is created in the nucleus and ejected from the nucleus. This electron is the β^- particle which has the mass and charge of an electron. β^- particles have a short range (~ 3 m in air). They are more penetrating than alpha-particles and can be shielded by low- Z materials like plastic or thin metals. From a health physics perspective, β^- can be an internal hazard and pose a predominant risk to the skin and eye exposure pathways.

An example of β^- is the decay of ${}^{60}_{27}\text{Co}$

Similar to the computation of Q -value for alpha decay, the energy released is the mass-energy difference between the parent, daughter, and β^- particle.

$$Q = M_P - (M_D + M_e) = \Delta_P - \Delta_D \quad (18)$$

where M_P and M_D are the nuclear masses, and M_e is the mass of an electron, assuming that electron binding energy is neglected. Therefore, for β^- decay to be energetically possible, $M_P > (M_D + m)$. For the decay of ${}^{60}_{27}\text{Co}$, the Q -value energy released is 2.82 MeV. In β^- , the energy released is distributed among three products: the daughter nucleus, the β^- particle, and the antineutrino. Because of the relatively large mass of the recoil daughter nucleus, it receives very little kinetic energy. Therefore, the kinetic energy is distributed primarily between the β^- (E_{β^-}) and the antineutrino ($E_{\bar{\nu}}$). However, depending on the relative direction of the momenta of each of the three decay products, E_{β^-} and $E_{\bar{\nu}}$ vary between 0 and Q , which means E_{β^-} exists as a continuous energy spectrum with an average $E_{\beta^-} \sim Q/3$. This is in contrast to alpha decay, where the alpha particle has a single discrete energy, on account of the two-body product of alpha decay.

The decay scheme for ${}^{60}_{27}\text{Co}$ is given in Fig. 7. Over 99% of ${}^{60}_{27}\text{Co}$ undergoes β^- decay emitting a β^- with $E_{\beta^-} \sim Q/3 = 0.318/3 = 0.106$ MeV. Following the β^- , the daughter ${}^{60}_{28}\text{Ni}$ nucleus is still in an excited state, and de-excites to a stable ground state through the emission of two characteristic gamma-rays at 1.173 and 1.332 MeV. The ${}^{60}_{27}\text{Co}$ β^- , also decays via a rare mode of an excited state of ${}^{60}_{28}\text{Ni}$, with only the single 1.332 MeV gamma-ray emission to de-excite to the ground state.

A number of pure β^- emitters exist, meaning that they have no accompanying gamma rays, including ${}^3\text{H}$, ${}^{14}\text{C}$, ${}^{32}\text{P}$, ${}^{90}\text{Y}$, and ${}^{90}\text{Sr}$. Some mixed beta-gamma emitters include ${}^{60}\text{Co}$, ${}^{137}\text{Cs}$, and ${}^{131}\text{I}$.

β^+ Positron decay

Positron (β^+) decay occurs in particles that are proton rich. These proton rich nuclei gain stability by increasing the N/Z ratio by converting a proton to a neutron. In β^+ decay, a neutrino (ν) and a positron (${}^0_{+1}e$) are emitted from the nucleus, where A remains the same as with β^- decay:

Fig. 7 β^- decay scheme of ${}^{60}_{27}\text{Co}$. Reproduced from Turner JE (2008) Atoms, Radiation, and Radiation Protection. John Wiley & Sons.

In essence,

$${}_1^1p \rightarrow {}_{+1}^0e + {}_0^1n + {}_0^0\nu \quad (20)$$

where a positron (the antiparticle of an electron with the same mass) is created (instead an electron as in β^- decay) and ejected from the nucleus.

An example of β^+ is the decay of ${}_{11}^{22}\text{Na}$:

$${}_{11}^{22}\text{Na} \rightarrow {}_{10}^{22}\text{Ne} + {}_{+1}^0e + {}_0^0\nu + Q \quad (21)$$

Similar to the computation of Q -value for β^- decay, the energy released is the mass-energy difference between the parent and daughter plus electron, but must further account for 2 electron masses (M_e) in the mass-energy calculations.

$$Q = M_P - (M_D + 2M_e) = \Delta_P - \Delta_D - 2M_e c^2 \quad (22)$$

where M_P and M_D are the nuclear masses, and M_e is the mass of an electron, assuming that electron binding energy is neglected. Therefore, for β^+ decay to be energetically possible, $M_P > M_D + 2M_e$. Recall, $2M_e = 2 \times 0.511 \text{ MeV} = 1.022 \text{ MeV}$. For the decay of ${}_{11}^{22}\text{Na}$, the Q -value energy released is 1.821 MeV. One of the decay schemes for ${}_{11}^{22}\text{Na}$ is given in Fig. 8, depicting how the daughter nucleus, following β^+ decay, is still left in an excited state and must de-excite to the ground state with 100% probability through the emission of a 1.275 MeV characteristic gamma-ray. Note that β^+ is one of two possible decay modes of ${}_{11}^{22}\text{Na}$, where electron capture competes with positron decay (see discussion next in section [Electron capture](#)). Although not explicitly sketched in Fig. 8, all β^+ create two accompanying 0.511 MeV photons when they annihilate with electrons, which are emitted essentially back-to-back at 180° , with some dependence on momentum transfers. You may notice in Figs. 8 and 9 that ${}_{11}^{22}\text{Na}$ has energy levels of 2.843 and 1.820 MeV and that this energy difference of 1.022 MeV ($= 2 \times 0.511 \text{ MeV}$) equals the rest mass of two electrons. These annihilation photons originate from a positron undergoing annihilation with an atomic electron.

Fig. 8 β^+ Decay scheme of ${}_{11}^{22}\text{Na}$. Reproduced from Turner JE (2008) *Atoms, Radiation, and Radiation Protection*. John Wiley & Sons.

Fig. 9 EC decay scheme of ${}_{11}^{22}\text{Na}$. Reproduced from Turner JE (2008) *Atoms, Radiation, and Radiation Protection*. John Wiley & Sons.

Electron capture

Electron capture (EC) is a competing decay mode to β^+ decay for proton-rich nuclides in circumstances where β^+ decay is not energetically possible, i.e., where the $M_P > M_D + 2M_e$ energy conditions cannot be met. In EC, an atomic electron is captured by the nucleus, which transforms a proton (p) into a neutron (n) and an accompanying neutrino (ν) is emitted. EC has the same effect on the nucleus as β^+ decay:

$${}^A_Z P + {}^0_{-1} e \rightarrow {}^A_{Z-1} D + {}^0_0 \nu + Q \quad (23)$$

In summary:

$${}^1_1 p + {}^0_{-1} e \rightarrow {}^1_0 n + {}^0_0 \nu \quad (24)$$

Positron (β^+) decay occurs in radionuclides that are proton rich. These proton-rich nuclei gain stability by increasing the N/Z ratio by converting a proton into a neutron. In β^+ decay, a neutrino and a positron are emitted from the nucleus as a result of the transformation of a proton into a neutron, where A remains the same as with β^- decay:

$${}^A_Z P \rightarrow {}^A_{Z-1} D + {}^0_{+1} e + {}^0_0 \nu + Q \quad (25)$$

In essence,

$${}^1_1 p \rightarrow {}^0_{+1} e + {}^1_0 n + {}^0_0 \nu \quad (26)$$

In EC, nuclei capture an orbital electron, usually a K -shell electron, and must therefore overcome the binding energy (E_B) of the electron:

$$M_P + (M_e - E_B) \rightarrow M_D + Q \quad (27)$$

Therefore, the Q -value can be written as:

$$Q = M_P + M_e - (M_D + E_B) = \Delta_P - \Delta_D - E_B \quad (28)$$

For EC to be energetically possible, $M_P - M_D > E_B - M_e$.

Two EC decay schemes for ${}^{22}_{11}\text{Na}$ that compete with the β^+ from Fig. 8 are given in Fig. 9. The β^+ emission is the predominant decay mechanism, occurring 89.8% of the time, and EC occurring 10.2% of the time. In both EC cases, a gamma-ray with energy of 1.275 MeV occurs with 100% frequency, indicating that both β^+ and EC leave the daughter nucleus in an excited state, which must decay to a ground state through the emission of this characteristic gamma ray.

Given the mechanism of the capture of a (typically) K -shell electron, characteristic X-rays are also emitted in EC decay. The decay data for ${}^{22}_{11}\text{Na}$ is summarized (Table 1).

Gamma emission

Photon sources from radioactive transformations are ionizing forms of electromagnetic radiation. Photon emissions from radioactive transformations are distinguished as a function of their origin: (1) X-rays originate from de-excitation of electron orbital shells of an atom; (2) annihilation photons originate from positron/electron annihilation with energies of 0.511 MeV each; (3) bremsstrahlung originate from deceleration of electrons in matter (discussed later in detail in section **Light Charged Particles**); and (4) gamma rays emitted from the nuclei of excited daughter nuclides following radioactive transformations. Gamma rays (γ) generally have higher energies than characteristic X-rays. Gamma rays have no mass or charge, travel a long range in air (~ 100 m) before interacting. High- Z materials are required to shield gamma rays, where typical shielding materials employed are lead, steel, or concrete. From a health physics perspective, gamma rays are predominantly hazardous as an external total body source, but can also be internal hazards for gamma rays that deposit their energy within the body.

Nuclei that decay from an excited state with no change in the number of nucleons are called isomeric transitions (IT). Nuclides in the initial and final states are called isomers, and are denoted by (D^*) or (D^m), where " m " denotes a temporary, excited, "meta-stable" state. For each of the decay schemes discussed thus far, isomeric transition from an excited to ground state has occurred

Table 1 Decay data for ${}^{22}_{11}\text{Na}$ from β^+ and EC modes.

Decay mode	Average energy (MeV)	Probability
β^+	0.215 (max 0.545)	89.8%
β^+	0.8350	0.06%
β^+ annihilation	0.511	180%
γ	1.275	100%
Auger (K-shell e^-)	0.0008	9.20%
K-shell-X-ray	0.0008	0.13%

in the decay of $^{226}_{88}\text{Ra}$ accompanying alpha decay (see Fig. 6 in section **Alpha decay**); $^{60}_{27}\text{Co}$ following β^- decay (see Fig. 7 in section **β^- Decay**); and $^{60}_{27}\text{Co}$ following β^+/EC decay (see Fig. 8 in section **β^+ + Positron decay** and Fig. 9 in section **Electron capture**).

Unlike β -particles, which have an associated spectrum of β -energies, gamma rays emitted from the nucleus have discrete energies in an Γ to the ground state:

$$Q_{\Gamma} = M_P - M_D = \Delta_P - \Delta_D \quad (29)$$

Internal conversion

Internal conversion (IC) is an alternative pathway for excited nuclei to de-excite as a process of radioactive decay in which a nucleus in an excited state interacts electromagnetically with one of the atom's orbital electrons, resulting in emission of the electron from the atom. Emission of IC electrons always competes with emission of a photon (gamma ray) in de-excitation of excited states of nuclei. Unlike a β^- decay, which originates due to a transformation in the nucleus, the electron emitted in IC is from the orbital electrons (K- or L-shell, most likely). The energy of the ejected electron (E_e) is therefore equal to the difference between excess energy of the daughter nuclide E_{D^*} and the E_B is the binding energy of the atomic electron:

$$E_e = E_{D^*} - E_B \quad (30)$$

Just as with EC, the removal of orbital electron is followed by filling the gap in the orbital by an electron from a higher orbital, resulting in the emission of a characteristic X-ray.

Auger electrons

In an atom in which an L -shell electron transitions to fill a K -shell vacancy will not always emit a photon, especially in low- Z elements. Instead, a transition may occur in which an L -shell electron is ejected from the atom, thereby leaving two L -shell vacancies. These ejected electrons are referred to as Auger electrons, which an electron emitted from an atom when the energy produced by the filling of a vacancy in an inner shell with an electron from an outer shell of higher energy is transferred to another electron, rather than emitted as a characteristic X-ray. Auger electrons are produced in decay of many radionuclides. They also are produced when an inner-shell vacancy is created by irradiation of an atom by photons or electrons. The energy of the Auger electron is given by the difference of the binding energy of the inner shell (E_{B_i}) and twice the binding energy of the outer shell (E_{B_o}):

$$E_{\text{Auger}} = E_{B_i} - 2E_{B_o} \quad (31)$$

If an electron transitions from the L_I level into a K -shell vacancy, it will release an energy equal to the difference in binding energies ($E_K - E_{L_I}$), which can be transferred to an L_{III} electron. Therefore, the energy of the ejected Auger electron is equal to $E_K - E_{L_I} - E_{L_{III}}$.

Activity

The number of nuclear transformations (decays of radionuclides) occurring in a given quantity of material per unit time referred to as the activity. The SI unit of activity is the becquerel (Bq), which was named after Henri Becquerel, who discovered radioactivity in 1896. The unit of 1 Bq is 1 decay per second. The traditional unit of activity was the curie (Ci) named after Marie and Pierre Curie who discovered radium in 1898. This unit (1 Ci) is defined as the activity of 1 g of $^{226}_{88}\text{Ra}$, which is defined as 3.7×10^{10} Bq.

The process of radioactive decay can be mathematically represented as a first-order linear differential equation:

$$\frac{dN}{dt} = -\lambda N(t) \quad (32)$$

where N is the number of radioactive atoms and λ is a constant called the decay constant. The decay constant is the probability that a radionuclide will decay per unit time. The reciprocal of a decay constant ($1/\lambda$) is the mean (average) lifetime of a radionuclide. If at $t = 0$, the initial number of radioactive atoms is N_0 , the number of radioactive nuclei remaining after time t can be obtained by solving Eq. (32):

$$N(t) = N_0 e^{-\lambda t} \quad (33)$$

This is called the "radioactive decay law." This behavior is plot as a function of time in Fig. 10.

The activity, A (Bq), of a sample is related to the number of radioactive atoms present in the sample by the decay constant:

$$A(t) = \lambda N(t) \quad (34)$$

In terms of activity, Eq. (33) can be re-written as:

$$A(t) = A_0 e^{-\lambda t} \quad (35)$$

where A_0 is the initial activity at time, $t = 0$.

Fig. 10 Plot of radioactive decay law demonstrates the exponential decay of number of radioactive atoms to stable atoms; half-life is denoted as $T_{1/2}$ in this figure. Reproduced from Ling SJ, Sanny J and Moebs W (2019) *University Physics Volume 3*. OpenStax CNX. Available: <http://cnx.org/contents/af275420-6050-4707-995c-57b9cc13c358@12.2> (Accessed 2020).

Half-life

The period of time that a radioactive substance takes to decay to half of its initial amount (N_0) is called the half-life ($t_{1/2}$). After one half-life period has elapsed, 50% of the original number of atoms remain ($0.5 N_0$); after two half-life periods have elapsed, 25% of the original number of atoms remain ($0.25 N_0$); after three half-life periods have elapsed, 12.5% of the original number of atoms remain ($0.125 N_0$), etc.

The decay constant, λ , is related to the half-life, $t_{1/2}$, through the following relation:

$$t_{1/2} = \frac{\ln 2}{\lambda} \quad (36)$$

where $t_{1/2}$ is given in units of time (second, minutes, hours, days, years, etc.) and λ is given in units of inverse time (s^{-1} , h^{-1} , y^{-1} , etc.).

Measured half-lives can span from microseconds to billions of years. A list of radionuclides from natural, industrial, and medical sources/uses and their half-lives is summarized in **Table 2**.

Serial decay

Serial decay refers to a series of radioactive decay processes in which a parent radionuclide decays into one (or a successive series) of radionuclides before decaying to a stable isotope. For example, a serial decay case with a radioactive parent and a single intermediate radioactive daughter can be described as:

Table 2 Half-lives of commonly encountered natural, industrial, and medical radionuclides.

Source	Half-Life
<i>Natural radionuclides</i>	
Uranium-238	4.5 billion years
Thorium-232	14 billion years
Potassium-40	1.3 billion years
Radium-226	1600 years
<i>Industrial radionuclides</i>	
Cesium-137	30.17 years
Cobalt-60	5.271 years
Barium-133	10.5 years
Iridium-192	74 days
Americium-241	432.2 years
<i>Medical radioisotopes</i>	
Iodine-131	8.0 days
Thallium-201	3.0 days
Technetium-99m	6.0 h

where X_1 is a radioactive parent with decay constant λ_1 ; X_2 is a radioactive daughter with decay constant λ_2 ; and X_3 is a stable terminal daughter. To determine $N_1(t)$ of the parent radionuclide, X_1 , we may adhere to the solution to Eq. (32). However, the series of differential equations in Eq. (32) can be expanded to include the transformation of radioactive daughter X_2 to stable daughter X_3 .

$$\begin{aligned} N_1(t) &= N_1(0)e^{-\lambda_1 t} \\ \frac{dN_2}{dt} &= \text{Production} - \text{Decay} \\ \frac{dN_2}{dt} &= \lambda_1 N_1(t) - \lambda_2 N_2(t) \end{aligned} \quad (38)$$

where $N_2(t)$ is the number of radioactive atoms of the radioactive daughter, X_2 , at time t . For a general condition for a sample of X_1 with an initial number of radioactive atoms, $N_1(0)$, and for with an initial number of radionuclide X_2 of $N_2(0)$ yields the following solution to Eq. (38):

$$N_2(t) = N_1(0) \left[\frac{\lambda_1}{\lambda_2 - \lambda_1} \right] [e^{-\lambda_1 t} - e^{-\lambda_2 t}] + N_2(0)e^{-\lambda_2 t} \quad (39)$$

If there are no daughter nuclides initially present at $t = 0$ (i.e., $N_2(0) = 0$), such as from a fresh sample of just X_1 , then the second term in Eq. (39) crosses out.

If solving for the activity of X_2 by combining Eq. (34) and Eq. (39)

$$\begin{aligned} A_2(t) &= \lambda_2 N_2(t) \\ A_2(t) &= A_1(0) \left[\frac{\lambda_2}{\lambda_2 - \lambda_1} \right] [e^{-\lambda_1 t} - e^{-\lambda_2 t}] + A_2(0)e^{-\lambda_2 t} \end{aligned} \quad (40)$$

The general solution to serial decay for a chain of i radionuclides is given by the Bateman equations:

$$\frac{dN_i}{dt} = \lambda_{i-1}N_{i-1}(t) - \lambda_i N_i(t) \text{ for } (i = 2, n) \quad (41)$$

Radioactive equilibrium

Radioactive equilibrium for a decay chain occurs when each radionuclide decays at the same rate it is being produced. If the half-life of the daughter radionuclide is much longer than the parent, then equilibrium cannot occur.

There are three general cases for potential radioactive equilibrium.

Case 1: Secular equilibrium—The half-life of the parent is much larger than the daughter ($t_{1/2(1)} \gg t_{1/2(2)}$).

Case 2: Transient equilibrium—The half-life of the parent is approximately/greater than the half-life of the daughter ($t_{1/2(1)} \geq t_{1/2(2)}$).

Case 3: No equilibrium—The half-life of the parent is less than the daughter ($t_{1/2(1)} < t_{1/2(2)}$).

Case 1: Secular Equilibrium

Secular equilibrium is a case in which the half-life of the parent radionuclide is much larger than the half-life of the daughter. If $t_{1/2(1)} \gg t_{1/2(2)}$, then $\lambda_{1/2(1)} \ll \lambda_{1/2(2)}$. This means that $\frac{\lambda_2}{\lambda_2 - \lambda_1} \sim 1$ and $e^{-\lambda_1 t} \sim 1$ in Eq. (40) and simplifies to:

$$A_2(t) = A_1(0)[e^{-\lambda_1 t} - e^{-\lambda_2 t}] + A_2(0)e^{-\lambda_2 t} \quad (42)$$

After a period of ingrowth of $\sim 7t_{1/2(1)}$ and assuming at $A_2(0) = 0$, then secular equilibrium is reached where the condition $A_1(t) = A_2(t)$, i.e. $\lambda_1 N_1(t) = \lambda_2 N_2(t)$. Secular equilibrium is depicted in Fig. 11 (Oak Ridge Institute For Science Education, 2011).

A common example of secular equilibrium occurs during the double β^- decay of $^{90}_{38}\text{Sr}$, where $^{90}_{38}\text{Sr}$ is a product of nuclear fission from nuclear reactors, and it is found in the environment as a result of nuclear weapons tests (see section Fission).

In this decay chain, the parent $^{90}_{38}\text{Sr}$ has a half-life of 29.12 y, and the daughter $^{90}_{39}\text{Y}$ has a half-life of 64.0 h before decaying to $^{90}_{40}\text{Zr}$ (stable). As $t_{1/2(^{90}_{38}\text{Sr})} \gg t_{1/2(^{90}_{39}\text{Y})}$, the assumptions and simplifications of the serial decay equation apply, resulting in a case of secular equilibrium.

Case 2: Transient Equilibrium

Transient equilibrium is a case encountered in which the half-life of the parent is slightly greater than the half-life of the daughter. If $t_{1/2(1)} \geq t_{1/2(2)}$ then $\lambda_{1/2(1)} < \lambda_{1/2(2)}$. No simplification to the general solution is possible, but the behavior of $\frac{A_2(t)}{A_1(t)} = \frac{\lambda_2}{\lambda_2 - \lambda_1}$. This means that after $\sim 10t_{1/2(1)}$, and assuming $A_2(0) = 0$, then $e^{-\lambda_2 t}$ becomes negligible and A_1 and A_2 exist in a constant ratio to each other. Transient equilibrium differs from secular equilibrium in that significant decay of the parent takes place and the activity of the decay product is greater than the activity of the parent. Transient equilibrium is depicted in Fig. 12.

Fig. 11 Activity of parent and daughter in secular equilibrium. Equilibrium conditions occur where $A_1(t) = A_2(t)$ after a period of ingrowth of $\sim 7t_{1/2(1)}$. Reproduced from Oak Ridge Institute For Science Education (2011) *Radiological and Chemical Properties of Uranium*. US Nuclear Regulatory Commission.

Fig. 12 Activity of parent and daughter in transient equilibrium. Equilibrium conditions occur $A_2(t)/A_1(t) = \text{constant ratio}$ after a period of ingrowth of $\sim 10t_{1/2(1)}$. Reproduced from Oak Ridge Institute For Science Education (2011) *Radiological and Chemical Properties of Uranium*. US Nuclear Regulatory Commission.

An example of transient equilibrium is the elution of the medical isotope, $^{99m}_{43}\text{Tc}$, where $^{99}_{42}\text{Mo}$ β^- decays into an excited metastable state $^{99m}_{43}\text{Tc}$, before emitting a 0.15 MeV gamma ray. $^{99m}_{43}\text{Tc}$ radiopharmaceuticals are used in medical diagnoses, including cardiac studies and bone scans.

In this decay chain, the parent $^{99}_{42}\text{Mo}$ has a half-life of 65.94 h, and the daughter $^{99m}_{43}\text{Tc}$ has a half-life of 6.02 h before decaying to $^{99}_{43}\text{Tc}$ (stable). As $t_{1/2}(^{99}_{42}\text{Mo}) \geq t_{1/2}(^{99m}_{43}\text{Tc})$, following an extended period of ingrowth, both $^{99}_{42}\text{Mo}$ and $^{99m}_{43}\text{Tc}$ reach transient equilibrium, and hold a constant ratio of their activities. This property makes it possible to elute $^{99m}_{43}\text{Tc}$ in hospitals for medical diagnostics onsite in hospitals through the use of "generators."

Case 3. No Equilibrium

In the case where the half-life of the parent is less than the daughter ($t_{1/2(1)} < t_{1/2(2)}$), then the parent rapidly decays while the daughter builds to a maximum before decaying away due to its own half-life. This is depicted in Fig. 13.

A case in which no equilibrium conditions exist is the alpha decay of $^{218}_{84}\text{Po}$, which exists in the $^{222}_{86}\text{Rn}$ decay chain originating from $^{238}_{92}\text{U}$.

In this decay chain $^{218}_{84}\text{Po}$ undergoes alpha decay with a half-life of 3 min to $^{214}_{82}\text{Pb}$, which β^- decays with a half-life of 27 min to $^{214}_{83}\text{Bi}$. Since $t_{1/2}(^{218}_{84}\text{Po}) < t_{1/2}(^{214}_{82}\text{Pb})$, no equilibrium conditions are met.

Fig. 13 Activity of parent and daughter where no equilibrium conditions are met. The parent rapidly decays as the daughter grows during the period of ingrowth, after which the daughter decays away at the rate governed by its own half-life, with no new production from the parent. Reproduced from Oak Ridge Institute For Science Education (2011) *Radiological and Chemical Properties of Uranium*. US Nuclear Regulatory Commission.

Photon interactions

Photons are electromagnetic waves having no charge or mass but exhibit both particle and wave-like behavior. Photons are emitted through radioactive decay to de-excite the atom through the emission of characteristic X-rays or the nucleus through the emission of gamma-rays. The distance the photon travels is dependent on the photon energy and on the material through which it is traversing, which may be estimated by probability of interaction per unit distance. Since photons are a form of indirectly ionizing radiation, interactions with an intermediary charged particle, i.e., electron, are the mechanism by which energy is deposited. The effect of a photon interacting in matter can yield three possible results per interaction: complete absorption of the photon; elastic scattering of the photon; or inelastic scattering of the photon. These behaviors are observed in the five major types of photon interactions.

Rayleigh (coherent) scattering

Rayleigh (or "coherent") scattering occurs when photons are scattered by very small particles (less than $\sim 1/10$ th of the wavelength of the photon). This phenomenon is of interest in some physics experiments, but not of much interest for health physics since no net energy is transferred to a charged particle, nor does any ionization or excitation occur to contribute to dose.

Photoelectric effect

The photoelectric effect was explained by Einstein (1905) as an absorption process in which an incident photon (gamma ray or X-ray) ejects an electron from an atom, with all the photon energy absorbed in ejecting the electron and imparting kinetic energy to it. A characteristic X-ray or an Auger electron then is produced when the vacated shell is filled by another orbital electron from a higher shell. Einstein was awarded the 1921 Nobel Prize in Physics "his discovery of the law of the photoelectric effect" (Nobel Foundation, 2020).

The relationship between the energy, frequency, and wavelength of electromagnetic radiation according to the equation derived by Max Planck (Planck, 1901) and harnessed by Albert Einstein to explain the photoelectric effect (Einstein, 1905) in Eq. (46):

$$E = h\nu = \frac{hc}{\lambda} \quad (46)$$

Photoelectric interactions occur when a photon with a given energy, E , interacts with a tightly bound atomic electron resulting in the absorption of the photon and the ejection of an electron, called the photoelectron. The maximum kinetic energy of the photoelectron, T , is equal to the incident photon energy less the energy required for the bound electron to escape:

$$T = h\nu - \phi \quad (47)$$

The energy required for the electron to escape from the surfaces called the work function, ϕ . This minimum energy must overcome attractive forces. Momentum is conserved by the photoelectron and the recoil atom.

The probability of photoelectric interaction occurring increases rapidly with the binding energy, with the greatest probability of an incident photon undergoing a photoelectric interaction if the photon has low energy, $h\nu$, and interacting in a high- Z material. The resulting vacancy left in the atom from the ejection of the photoelectron results in filling from an outer shell electron; the change of transition energy to fill the vacancy thus results in the emission of fluorescent radiation, i.e., a characteristic X-ray. Consequently, approximately 80% of photoelectric absorption processes take place in the K -shell of atomic electrons.

Compton effect

In 1922, Arthur Holly Compton was conducting scattering experiments using molybdenum K_{α} X-rays ($E = 17.4$ keV) directed at a graphite target, where the wavelength of the incident and scattered were measured (Compton, 1922). It was found that the energy of the scattered photon varied as a function of photon scattering angle following a scattering interaction with an electron. This discovery challenged the traditional notion that the incident and scattered photon wavelengths should remain unchanged. By demonstrating that light could not be explained as purely a wave phenomenon, the experimental results implied that the photon had particle-like behavior. This interaction in which an incident photon scatters from an orbital electron in an atom to produce a recoil electron, a residual ionized atom, and a photon of energy less than the energy of the incident photon was called the Compton effect. Compton was awarded the Nobel Prize in Physics in 1927 “for his discovery of the effect named after him” (Nobel Foundation, 2020).

Compton interactions are photon scattering interactions with an orbital electron, when the electron struck by the incoming photon is unbound and stationary. Although, the electrons are not “completely free,” so the binding energies have a very small relative impact on the energy transfer (Fig. 14).

The kinematics of Compton scattering conserve both energy and momentum before and after interaction. The energy of the recoil electron (rest mass $m_e c^2$) is given by T at an angle φ and energy of the scattered photon by $h\nu'$ at an angle θ with respect to the incident photon direction.

$$h\nu' = \frac{h\nu}{1 + \left(\frac{h\nu}{m_e c^2}\right)(1 - \cos\theta)} \quad (48)$$

where

$$T = h\nu - h\nu' \quad (49)$$

When the scattering angle of the photon (θ) is small, the scattered photon travels in the forward direction, imparting little energy to the electron, which moves off at nearly right angles to the direction of the incident photon. As the photon scattering angle increases from 0° to 180° (the maximum scattering angle), the recoil electron angle (φ) decreases from 90° to 0° .

At low photon energies, Compton scattering is not an efficient method of energy transfer, compared to higher photon energies. Let us compare the fraction of the maximum energy transferred (T) to the Compton electron (at angle of $\theta = 180^\circ, \varphi = 0^\circ$) from a 5.11 keV incident photon vs. a 5.11 MeV incident photon. If we use Eqs. (48) and (49) to determine the fraction of incident photon energy transferred to the Compton electron ($T/h\nu$), Table 3 demonstrates that Compton interactions for low energy photons are a poor mechanism of energy transfer to charged particles compared to higher energy photons.

Fig. 14 Compton scattering kinematics of incident photon with a free electron at rest. Following the collision, the photon is scattered at an angle θ with an energy $h\nu'$ and the electron at with an energy T and angle φ .

Table 3 Comparison of fraction of energy transferred from low and high energy incident photons to a Compton electron through Compton scattering.

Photon energy, 5.11 keV	Photon energy, 5.11 MeV
$\alpha = \frac{5.11 \text{ keV}}{0.511 \text{ MeV}} = 0.010$	$\alpha = \frac{5.11 \text{ MeV}}{0.511 \text{ MeV}} = 10$
$E_{e(\max)} = 5.11 \text{ keV} \times \left(2 \times \frac{0.01}{1.02}\right)$	$E_{e(\max)} = 5.11 \text{ MeV} \times \left(2 \times \frac{10}{21}\right)$
$= 0.10 \text{ keV}$	$= 4.87 \text{ MeV}$
$h\nu'(\min) = 5.11 \text{ keV} \times \frac{1}{1.02}$	$h\nu'(\min) = 5.11 \text{ MeV} \times \frac{1}{21}$
$= 5.01 \text{ keV}$	$= 0.24 \text{ MeV}$
Energy transferred: 2%	Energy transferred: 95%

Pair production

Pair production is an absorption process in which an incident photon is annihilated in close proximity to an atomic nucleus, producing an electron and positron pair. This process occurs at incident photon energies greater than the rest-mass energy of an electron and positron combined ($h\nu \geq 2m_e c^2$). This phenomenon was observed in the cloud chamber experiments of Patrick Maynard Stuart Blackett, resulting in the 1948 Nobel Prize “for his development of the Wilson cloud chamber method, and his discoveries therewith in the fields of nuclear physics and cosmic radiation” (Nobel Foundation, 2020).

The threshold energy required for the observed reaction is twice the rest mass of an electron, resulting in the conversion of the photon into an electron-positron pair in the field of the atomic nucleus (Fig. 15).

When pair production occurs in the nuclear field, the nucleus has a negligible recoil kinetic energy. This results in the incident photon energy being converted into an electron and positron (masses $2m_e c^2$) with remaining kinetic energy distributed as T^+ and T^- between both the positron and electron, respectively. The kinetic energy distribution of the positron and electron can vary from 0 to $h\nu - 2m_e c^2$. At the end of the positron's flight path, the positron will slow and attract an electron to form an electron-positron complex called positronium, lasting 10^{-10} s before annihilating into two photons with energy $m_e c^2$ (0.511 MeV). Conservation of energy in the nuclear field from pair production becomes:

$$h\nu = 2m_e c^2 + T^+ + T^- \quad (50)$$

where the average kinetic energy ($\bar{T}$) imparted to each of the electron and positron is:

$$\bar{T} = \frac{h\nu - 2m_e c^2}{2} \quad (51)$$

Pair production can also occur in the atomic electron field (called “triplet” production, but with a lower probability and higher photon threshold minimum energy of ($h\nu \geq 4m_e c^2$)). In the electron field, the incident photon distributes its energy between the electron-positron pair, as well as the additional host electron. Conservation of energy in the electron field from pair production becomes:

$$h\nu = 2m_e c^2 + T^+ + T_1^- + T_2^- \quad (52)$$

where the average kinetic energy ($\bar{T}$) imparted to each of the three particles is:

$$\bar{T} = \frac{h\nu - 2m_e c^2}{3} \quad (53)$$

Photonuclear interactions

At very high photon energies, a photon can be absorbed in the nucleus, excite the nucleus, and liberate a nucleon (proton or neutron) through the process of photo-disintegration, which is known as a photonuclear interaction. Analogous to the photoelectric effect, the incident photon must have sufficient energy to overcome the threshold of the large binding energy of the nucleon, which, referring back to Fig. 3, is in the order of several MeV. The probability of photonuclear interactions, overall, is orders of magnitude lower than the combined probability of the photoelectric effect, Compton effect, and pair production combined.

Two interactions from photonuclear disintegration can occur: (γ, n) and (γ, p). The threshold energy for (γ, p) exceeds that of (γ, n) due to the required energy to overcome the Coulombic barrier a photon must overcome to escape the nucleus. From a health physics perspective, the (γ, p) events contribute to dose, though only $< 5\%$ due to the dominance of pair production. The (γ, n) interaction is of more practical importance from a health physics perspective, with neutrons leading to further challenges in radiation protection

Fig. 15 Pair production interaction from an incident photon with energy $\geq 2m_e c^2$ interacting in the nuclear field, converting into an electron and a positron. The positron annihilates into two back-to back characteristic photons each with energy $m_e c^2$.

and more complex shielding design compared to just shielding considerations for γ -rays alone. Furthermore, (γ, n) become unwanted secondary effects in the use of high-energy radiotherapy beams.

Linear attenuation coefficient

Indirectly ionizing radiation (as photons or neutrons) have a high probability of traversing matter without interacting. As such, unlike charged particles, these uncharged particles are not characterized as having a range, but rather have a probability of interaction per unit path length. In the case of photons, these interactions are predominantly photoelectric effect, Compton scattering, or pair production. If it is assumed that a narrow beam of monoenergetic photons impinges perpendicularly on a flat plate of thickness, x (units of cm) and that each photon is completely absorbed in a single interaction without producing secondary radiation, the probability per unit path length that the photon will travel before interacting is defined by the linear attenuation coefficient, μ (units of cm^{-1}) (Fig. 16).

The probability that the photon will interact in an infinitesimal thickness dx becomes μdx . If N particles are incident upon the slab of thickness dx , the change (dN) in the number of photons impinging (N) due to absorption in the slab becomes:

$$dN = -\mu dx \quad (54)$$

To find the total change in the number of particles due to absorption in the slab of thickness x , we integrate over both sides of Eq. (54):

$$\int_{N_0}^{N_x} \frac{dN}{N} = - \int_0^x \mu dx \quad (55)$$

$$N(x) = N_0 e^{-\mu x} \quad (56)$$

where N_0 is the number of photons impinging on the slab and N_x is the number of photons transmitted through a slab of thickness, x . The number of transmitted photons is exponentially attenuated as a function of the thickness of the slab and the linear attenuation coefficient (which is defined for the photon energy). The number of interactions that occur are therefore equal to the difference of the number of incident and transmitted photons, $N_0 - N(x)$.

The average distance traveled between collisions is referred to as the mean free path, $1/\mu$ (units, cm). In health physics, the half-value layer (HVL) is the amount of material needed (x) to absorb 50% of the incident photons, where the tenth-value layer (TVL) is the amount of material needed to absorb 90% of the radiation i.e., reduce it to one-tenth of the original intensity.

Plural modes of absorption

If more than one absorption process is present, the total linear attenuation coefficient can be written as a sub of the constituent parts

$$\mu = \mu_1 + \mu_2 + \dots \quad (57)$$

where μ_1, μ_2 , etc., are called the partial linear attenuation coefficients for process 1, process 2, etc. For each constituent process, it is assumed that each event is totally absorbing and that it produces no secondary particles or interactions (e.g., scattering). Therefore, number of interactions due to a single process, for example μ_1 , alone is:

$$\Delta N = (N_0 - N(x)) \frac{\mu_1}{\mu} = N_0 (1 - e^{-\mu x}) \frac{\mu_1}{\mu}$$

where $\frac{\mu_1}{\mu}$ is the fraction of interactions that occur by process 1. The same analog can be made for μ_2 due to process 2, etc.

The linear attenuation coefficient for photons of a given energy in a specific material is composed of the individual contributions from the physical processes that can remove photons from the narrow beam, i.e., photoelectric effect, Compton scatter, and pair production (Rayleigh scattering and photonuclear interactions could be included, but due to the low probability of interaction, can be omitted for the purposes of this discussion).

$$\mu = \tau + \sigma + \kappa \quad (58)$$

Fig. 16 A narrow monoenergetic parallel beam of photons (N_0) impinging on a slab of thickness x will exponentially attenuate and transmit $N(x)$ photons governed by $N(x) = N_0 e^{-\mu x}$, where μ is the linear attenuation coefficient defined as a function of absorber material and incident photon energy.

where μ is the total interaction probability, linear attenuation coefficient; τ is the photoelectric interaction probability; σ is the Compton interaction probability; and κ is the pair production interaction probability (all in units cm^{-1}).

Fig. 17 shows the relative importance of each of the three major photon interaction mechanisms as a function of absorber material with (Z) electrons per atom and photon energy ($h\nu$), and it outlines the region where each interaction dominates. Lines where $\tau = \sigma$ and $\sigma = \kappa$ mark where two types of interactions have equal probability. At low photon energies and low Z , the photoelectric effect dominates, where at higher energies, pair production dominates. In the low- Z region, Compton interactions dominate over a broad region of 20 keV to 30 MeV, and narrows as a function of increasing Z .

Mass attenuation coefficient

The attenuation coefficient can be normalized as a function of density, ρ (g/cm^3) to yield the quantity of the mass attenuation coefficient (μ/ρ) in units cm^2/g . Just as in Eq. (58), the mass attenuation coefficient is the sum of the photoelectric mass attenuation coefficient, Compton mass attenuation coefficient, and pair production mass attenuation coefficient.

$$\frac{\mu}{\rho} = \frac{\tau}{\rho} + \frac{\sigma}{\rho} + \frac{\kappa}{\rho} \quad (59)$$

Fig. 18 shows the plot of the total mass attenuation coefficient and the constituent interaction coefficients for photoelectric effect, coherent (Rayleigh) scattering, incoherent (Compton) scattering, and pair production in both the nuclear and electron fields (Berger et al., 2010). The sum of the pair production coefficients in the nuclear and electron fields yields the total pair production mass attenuation coefficient. As shown in Fig. 17, the probability of each interaction occurring varies as a function of photon energy and Z of the interacting absorber. The total and constituent mass attenuation coefficients are given for carbon, lead, and water in Fig. 18.

In Fig. 18c, a prominent K -edge of Pb is given at 88 keV. At this energy, the two K -shell electrons cannot participate in the photoelectric effect because binding energy is too large to overcome. Only the L -shell, M -shell, and higher shell electrons can participate in photoelectric interactions in Pb. Just above 88 eV, K -electrons can also participate. The magnitude of step function from 7.1 to $1.7 \text{ cm}^2/\text{g}$ indicates the importance of contributions of two- K -shell electrons in photoelectric cross-section, compared to other the 80 electrons in Pb atom.

Mass energy absorption and mass energy transfer coefficients

In health physics, we are interested in the energy absorbed in matter from a source of photons. The energy absorbed in a material (e.g., shield, tissue, etc.) is related to the linear attenuation coefficient. A photon interaction will, in general, result in transfer of energy to a short range particle (mostly electrons). Energy will be absorbed from photon absorption interactions, such as photoelectric effect and pair production, and transferred to electrons by Compton scattering interactions. The energy transferred to the electron may be absorbed within the material, or it may leave the region of interest. The energy transferred to charged particles is described by the photon energy transfer coefficient, and the fraction of the charged particle energy that results in local energy deposition (i.e., dose deposition) excluding radiative losses by charged particles (discussed in section, **Light Charged Particles**) is given by the photon energy absorption coefficient.

If we expand upon Eq. (59), the total mass energy transfer coefficient (μ_{tr}/ρ) for a photon of incident energy $h\nu$ is equal to the sum of the constituent transfer interactions.

$$\frac{\mu_{tr}}{\rho} = \frac{\tau_{tr}}{\rho} + \frac{\sigma_{tr}}{\rho} + \frac{\kappa_{tr}}{\rho} \quad (60)$$

Fig. 17 Probability of photoelectric effect (τ), Compton scatter (σ), and pair production (κ) as a function of photon energy ($h\nu$) and Z of absorber. Lines where $\tau = \sigma$ and $\sigma = \kappa$ mark where two types of interactions have equal probability. Reproduced from Attix FH (2008). *Introduction to Radiological Physics and Radiation Dosimetry*. John Wiley & Sons.

Fig. 18 Total mass attenuation coefficients (cm²/g) for (a) carbon ($Z = 6$); (b) water; and (c) lead ($Z = 82$). Total coefficient is broken down into coherent (Rayleigh) scattering; incoherent (Compton) scattering; photoelectric absorption; and pair production in nuclear (double) and electron (triplet) fields. Generated from Berger M, Hubbell J, Seltzer S, Chang J, Coursey J, Sukumar R, Zucker D and Olsen K (2010) *XCOM: Photon Cross Sections Database*, NIST Standard Reference Database 8 (XGAM). Available: <https://www.nist.gov/pml/xcom-photon-cross-sections-database> (Accessed 2020) at NIST.gov.

In each of the photoelectric, Compton, and pair production interactions, the transfer coefficient is the product of the total attenuation coefficient for the interaction multiplied by the fraction of the incident photon energy transferred to electrons (Turner, 2008), summarized in Table 4.

To define the mass energy absorption coefficient, $\frac{\mu_{en}}{\rho}$, we must first define g to represent the average fraction of the initial photon energy transferred to charged particles, that are subsequently emitted as radiative interactions, i.e., bremsstrahlung (discussed in section Light Charged Particles). Therefore, the mass energy absorption coefficient can be defined as:

$$\frac{\mu_{en}}{\rho} = \frac{\mu_{tr}}{\rho} (1 - g) \quad (61)$$

The mass absorption coefficient ($\frac{\mu_{ab}}{\rho}$) is the most important parameter for the calculation of dose. For high- Z absorbers, g is largest. For low- Z absorbers and high photon energies, $g \rightarrow 0$. Therefore, $\frac{\mu_{en}}{\rho} \sim \frac{\mu_{tr}}{\rho}$ for low- Z and low incident photon energies. This is summarized for our examples of C ($Z = 6$) and Pb ($Z = 82$) in Table 5 and retrievable at Hubbell and Seltzer (1996).

Neutrons

Scattering interactions

Interactions of neutrons with matter may occur by scattering with nuclei or by absorption. In the case of scattering, the neutron experiences a billiard ball-type collision, where the kinetic energy of the neutron and nucleus are the same before and after the collision, or it may interact with the internal energy of the nucleus and be emitted from the nucleus. Neutrons undergo either absorption or scattering reactions with nuclei. If a neutron is absorbed into the nucleus, it may decay by a variety of mechanisms. It may fission, eject one or more neutrons, undergo alpha particle decay, emit a photon, decay by ejecting a proton, etc. Scattering may be elastic or inelastic. Elastic scattering may be well-defined by two particle kinematics or it may be a resonance phenomenon. Inelastic scattering occurs when the neutron is absorbed and one is emitted with an isotropic angular distribution. This may or may not be a resonance phenomenon.

For the case of absorption, a compound nucleus is formed that may decay through a variety of channels, as illustrated by Eq. (62).

where

$$({}_Z^{A+1}X)^* \begin{cases} {}_0^1n + {}_Z^AX \text{ resonance elastic scattering} \\ {}_0^1n + ({}_Z^AX)^* \text{ inelastic scattering} \\ {}_Z^{A+1}X + \gamma \text{ radiative capture} \\ {}_Z^{A_1}X + {}_Z^{A_2}X + (2-3){}_0^1n \text{ fission} \end{cases}$$

Table 4 Mass energy transfer coefficients defined for photoelectric, Compton scatter, and pair production interactions.

Mass attenuation coefficient (cm^2/g)	Fraction of incident photon energy transferred to charged particles	Mass energy transfer coefficient (cm^2/g)
Photoelectric ($\frac{\tau}{\rho}$)	$1 - \frac{\phi}{h\nu}$ from Eq. (47)	$\frac{\tau_{tr}}{\rho} = \left(\frac{\tau}{\rho}\right) \left(1 - \frac{\phi}{h\nu}\right)$
Compton ($\frac{\sigma}{\rho}$)	$\frac{T_{avg}}{h\nu}$ from Eq. (49)	$\frac{\sigma_{tr}}{\rho} = \left(\frac{\sigma}{\rho}\right) \left(\frac{T_{avg}}{h\nu}\right)$
Pair Production ($\frac{\kappa}{\rho}$)	$1 - \frac{2m_0c^2}{h\nu}$ from Eq. (51)	$\frac{\kappa_{tr}}{\rho} = \left(\frac{\kappa}{\rho}\right) \left(1 - \frac{2m_0c^2}{h\nu}\right)$

Table 5 Relationship of mass energy transfer coefficient and mass energy absorption coefficient for low- Z and high- Z materials as a function of incident photon energy.

Incident photon energy, $h\nu$ (MeV)	$(\mu_{tr} - \mu_{en})/\mu_{tr}$	
	$Z = 6$	$Z = 82$
0.1	0%	0%
1.0	0%	4.8%
10	3.5%	26%

Several examples of neutron-nucleus reactions are shown in Eq. (63).

with other reactions of interest including, $(n, 2n)$, (n, p) , (n, α) , and (n, γ) .

Nuclear reactions follow the laws of conservation:

- The total number of nucleons (total A) is conserved.
- The total charge (total Z) is conserved.
- The total energy (including changes in total mass) is conserved.
- The total momentum is conserved.

Cross sections are the measure of the probability that a specific process will occur when an incident radiation interacts with an orbital electron or electrons or with the nucleus of atoms in a target material and can be conceptually considered as the size (area) of the object (atom or nucleus) an incident photon or particle must hit for an interaction of interest to occur. The interaction rate between neutrons and nuclei is determined by microscopic (σ) and macroscopic (Σ) cross-section. Microscopic cross-sections have units of area (cm^2) and macroscopic cross-sections have units of inverse length (cm^{-1}). Microscopic cross-sections are fundamental nuclear data that are functions of energy and depend on the energy structure of the nucleus and are often defined in units of barns (10^{-24} cm^2). The reaction rate (R) is the product of the microscopic cross section with the intensity of the neutron source and the number of target atoms per unit area, given in Eq. (64):

$$R \left[\frac{\text{interactions}}{\text{cm}^2 \cdot \text{s}} \right] = \sigma \left[\text{cm}^2 \right] \cdot I \left[\frac{\#}{\text{cm}^2 \cdot \text{s}} \right] \cdot N_A \left[\frac{\#}{\text{cm}^2} \right] \quad (64)$$

Fig. 19 illustrates the concept of a microscopic cross-section as the interaction probability between a neutron of intensity I and an individual particle or nucleus in a material one layer of atoms thick in dx .

Macroscopic cross-sections are calculated from known compositions and microscopic cross-section. Eq. (65) defines microscopic cross-sections and Eq. (66) illustrates the total microscopic (absorption plus scattering) with a breakdown of components for scattering (elastic and inelastic) and of absorption.

$$\sigma = \frac{R/N_A [\text{number of reactions/nucleus/s}]}{I [\text{number of incident neutrons/cm}^2/\text{s}]} \quad (65)$$

The total cross section (σ_t) is the sum of absorption (σ_a) and scattering (σ_s) interactions. Scattering interactions can be further broken down as the sum of elastic and inelastic energy transfer, where elastic scattering behaves like a billiard-ball type collision and inelastic scattering results in compound nucleus formation, $\sigma_m = X(n, n')X$. The absorption cross section is the aggregate sum of fission, radiative capture, etc. from $(n, 2n)$, (n, p) , (n, α) , (n, γ) neutron interactions. The total cross section can therefore be written as:

$$\sigma_t = (\sigma_e + \sigma_{in}) + (\sigma_f + \sigma_\gamma + \sigma_{n\alpha} + \sigma_{np} + \sigma_{n,2n} + \dots) \quad (66)$$

Fission

When a compound nucleus of a fissionable isotope is formed, it may energetically disintegrate into two or more lower-mass elements (fission) or it may transmute to another element or isotope and emit radiation that corresponds to the transition that occurs. Fissionable isotopes are those that may fission when a compound isotope is formed with a neutron of some kinetic energy, whereas fissile isotopes are those that will fission after the formation of a compound nuclide of zero kinetic energy. Examples of practical fissile isotopes include ^{235}U , ^{239}Pu , and ^{233}U . Both ^{238}U and ^{232}Th are examples of useful fissionable isotopes that will fission if the kinetic energy of the neutron that forms the compound is about 1 MeV. The kinetic energy of the recoil fission products, neutrons, neutrinos, and other radiative products may be calculated from binding energy per nucleon versus mass data, as illustrated in Fig. 3. Fig. 20 depicts the fission cross-section for ^{235}U with a strong characteristic resonance structure (Pritychenko et al., 2006). When the kinetic energy of the neutron-nucleus system corresponds to an energy level in the compound nucleus to be formed then the effective size of the compound nucleus may increase by several orders of magnitude.

The energy distribution of neutrons emitted during the fission of ^{235}U is illustrated by Fig. 21 (US Department of Energy, 1993).

Fig. 19 Microscopic cross-section (σ) depicting the probability of a neutron interacting in an infinitesimal layer one atom thick.

Neutron reactions in tissue

A number of neutron reactions are important in various aspects of health physics and radiation protection. This is governed by capture interactions with large neutron cross sections, often accompanied by a photon. The magnitude of the cross section, efficiency of energy transfer, and the abundance of hydrogen in soft tissue, neutron-proton (n,p) scattering is the dominant method

by which fast neutrons deliver dose to the tissue. Over 85% of “first collision” dose in soft tissue, comprising hydrogen, carbon, oxygen and nitrogen, originate from (n, p) scattering for neutrons < 10 MeV.

Slow and thermal neutrons interacting through capture interactions are dominated in the body by two key interactions. First, is the (n, γ) reaction in the body of $^1\text{H}(n, \gamma)^2\text{H}$, which releases a highly energetic gamma-ray with $Q = 2.22$ MeV. The energetic gamma will not be a localized dosimetric risk in a small tissue sample, but will rather pose a notable hazard over larger regions, such as that of the whole body. Comparatively, the second reaction of interest is the $^{14}\text{N}(n, p)^{14}\text{C}$ interaction, with a $Q = 0.626$ MeV. This interaction poses more of a localized risk, as the ^{14}C and proton deposit their energy locally at the site where the neutron is absorbed. Neutron capture by both ^1H and ^{14}N represent the predominant mechanism by which thermal neutrons deliver significant dose to soft tissue. Fast neutrons interact predominantly via elastic scattering in H, O, C, and N in soft tissue.

Charged particle interactions

Nuclei have diameters that range from about 1.6 to 15 fm (10^{-15} m), and the distance between them in solid materials is about an Angstrom (10^{-10} m); thus, this distance is about 100,000 times greater than the diameter of an alpha particle. The inter-nuclear space is populated with negatively charged electrons that govern the energy loss rate of charged particles to the medium through which it passes. This energy loss rate depends on charge and momentum of the charged particle and on the electron density of the medium through which it is passing. Two-particle kinematic models that utilize conservation of energy and momentum show that the energy transfer from a proton with an electron in a single collision is a fraction of a percent of the initial energy of the proton when its energy is less than 10 MeV (Turner, 2008).

Heavy charged particles

Positively charged particles transfer energy to electrons through several mechanisms. The dominate mechanism through electrostatic attraction of electrons that results in ionization of the nucleus and transfer of kinetic energy to electrons.

The rate of energy loss is referred to as stopping power ($-dE/dx$), and an example of this function for a proton is shown in Fig. 22 (Provision Health Care, 2020). You may notice that the energy loss rate is close to a linear function for about one-half of its total track length. When the range of the is about three-fourth of its way to the end of its track it forms a Bragg peak. The Bragg peak is the peak on a curve of the energy loss of ionizing radiation during a charged particle’s travel through matter. For protons, alpha particles, and other ions, the peak is quite pronounced and occurs close to the terminal point of the path of travel. The prominent feature of the Bragg peak makes proton therapy appealing due to its localized deposition of energy in target cancer cells with no exit dose to healthy tissue.

Niels Bohr (1885–1962) developed a formula for stopping power in 1913, without the benefit of quantum mechanics, that gave results within a few percent. Later, Bethe used relativistic quantum mechanics to obtain a more accurate formula for stopping power that depends on the following parameters:

Fig. 22 Comparison of radiation dose with depth of penetration in tissue of X-rays and protons. The prominent feature of the Bragg peak makes proton therapy appealing due to its localized deposition of energy in target cancer cells with no exit dose to health tissue. Reproduced from Provision Health Care (2020) *What Is Proton Therapy?* Available: <https://provisionhealthcare.com/about-proton-therapy/advantages-of-proton/>

- Atomic number of the heavy charged particle;
- Magnitude of the electron charge;
- Number of electrons per unit volume in the medium;
- Electron rest mass;
- Speed of light in a vacuum;
- The speed of the particle relative to light; and
- Mean excitation energy of the medium.

Stopping power depends only on the charge and velocity of the heavy charged particle and on properties through which the particle is passing. Bethe derived the following relationship for slowing down of charged particles (MeV/cm), using relativistic quantum mechanics:

$$-\frac{dE}{dx} = \frac{4\pi k_0^2 z^2 e^4 n}{mc^2 \beta^2} \left[\ln \frac{2mc^2 \beta^2}{I(1 - \beta^2)} - \beta^2 \right] \quad (67)$$

where $k_0 = 8.99 \times 10^9 \text{ N m}^2 \text{ C}^{-2}$, (the Boltzmann constant); z = atomic number of the heavy particle; e = magnitude of the electron charge; n = number of electrons per unit volume in the medium; m = electron rest mass; c = speed of light in vacuum; $\beta = v/c$ = speed of the particle relative to c ; I = mean excitation energy of the medium.

Range and slowing down rate

Heavy positively charged particles lose energy primarily through Coulombic interactions with electrons in the medium through which they are traveling. Loss through collisions with relatively very light electrons may be neglected. Alpha particles undergo continuous slowing down and consequently well-defined relationships exist between range and energy. The range of a heavy charged particle is obtained by integrating the stopping power from zero to the initial energy of the particle.

$$R(T) = \int_0^T \left(-\frac{dE}{dx} \right)^{-1} dE. \quad (68)$$

From Fig. 23, the range of a 10 MeV proton in water (density of 1.0 g/cm^3) is about 0.1 cm and for a 10 MeV alpha it is about 0.01 cm.

Fig. 23 Ranges of protons, alpha particles, and electrons in water, muscle, bone and lead, expressed in g cm^{-2} . Generated from <https://physics.nist.gov/PhysRefData/Star/Text/intro.html>.

Given the initial velocity, mass, and stopping power of a charged particle traveling through a given medium, it is relatively straightforward to calculate the time required to stop. For a proton of 1 MeV in water this time is 2.7×10^{-12} s (Turner, 2008), and the time for a 10 MeV proton it is 5×10^{-11} s. Chemical reactions of free radicals generated by proton or alpha particle irradiation are completed in less than a microsecond. This implies that diffusion times of free radicals is several orders of magnitude longer than the start to stop time of the irradiating particles.

The range of a 1 MeV alpha is about 8 μm (estimated from Fig. 23) and on the order of 100 μm for a 10 MeV alpha. Thus, an alpha of several MeV effectively creates a highly ionized cylindrical path over the distance of about five to 10 cell diameters. If about 2 MeV of energy is deposited over a volume of 100–1000 cells, about 50,000 ionizations could be generated. The spatial distribution would be very non-uniform since energy dissipates as a function of the cube of the radius; thus, an extremely rough estimate of the number of cells that would experience the contact of free radicals from this event could be on the order of 100–1000.

For the case of beta particles, that same amount of energy would be deposited over a much larger volume. As given in Fig. 22, the range of an electron is about 50 times longer than for an alpha particle; consequently, the corresponding volume would be about 100,000 times larger.

Light charged particles

The physics of slowing down electrons is different from that of positively charged heavy particles in several ways. One is that the mass of the irradiating beta particle (electron or positron) is the same as the electrons that fill the volume between nuclei (in a solid medium), and another is that the charges are the same. Another difference is that electrons lose energy by radiation and by collisions. Thus, the total stopping power for electrons is the sum of the collision stopping power and the radiative stopping power.

$$\left(-\frac{dE}{dx}\right)_{\text{tot}}^{\pm} = \left(-\frac{dE}{dx}\right)_{\text{col}}^{\pm} + \left(-\frac{dE}{dx}\right)_{\text{rad}}^{\pm} \quad (69)$$

The analytical expressions for these terms are complex and are not included here, but the interested reader may understand the details by consulting Attix (2008), Turner (2008), or Veinot (2019). In summary, the collisional component is due to “knock-on” collisions from incident electrons interacting with electrons in the target medium. The radiative component stems from the deceleration of the electron as it deposits its energy in the target medium, resulting in the release of photon energy known as bremsstrahlung. Bremsstrahlung (translated from German as “breaking radiation” is produced in a continuous energy spectrum by the deceleration of charged particles. Bremsstrahlung becomes a more pronounced feature of electron interactions in matter for both high-Z target materials, as well as high-energy electron sources. Bremsstrahlung is emitted as a characteristic spectrum of the source electron energy and target medium and becomes a radiation protection consideration with energetic beta/electron sources and particle accelerator shielding.

Beta particles do not follow a continuous slowing down model very well since electrons can lose large fractions of their energy in a single collision. However, the continuous slowing down model yields sufficiently accurate results that are very useful.

Restricted stopping power and linear energy transfer

When charged particles lose energy through Columbic interactions, they create ionizations and may transfer sufficient energy to an electron that travel much farther from the path of the charged particle than the length of the path of the charged particle that generated them. These electrons are referred to as delta rays, and they carry significant energy away from the path of the charged particle. One consequence of the delta-ray phenomena is that biological damage may occur sufficiently far from the location of the charged particle interaction that it should be considered a separate event. This phenomenon significantly complicates calculations of dose.

In order to account for delta rays and other phenomena that may result in energy of the primary particle being transported away from the site of initial interaction, the concepts of Restricted Stopping Power and Linear Energy Transfer (LET) have been found to be useful for dosimetric calculations. Stopping power is defined as the energy loss by a particle per unit path length of the particle. Restricted stopping power (Turner, 2008) is defined as the linear rate of energy loss due only to collisions in which the energy transfer does not exceed a specified value. It is obtained by integrating the weighted energy loss spectrum from a lower limit to the selected (or “restricted”) upper limit of integration. If the upper limit of integration is extended to infinity the result of this integration is the stopping power.

The concept of LET is defined slightly differently than restricted stopping power, but they may be numerically equivalent. LET was first defined in 1962 by the International Commission on Radiation Units and Measurements (ICRU) as the “average energy locally imparted”. The words “locally imparted” were not precisely defined so LET has not always been used with exactly the same meaning (Turner, 2008). In 1970, the ICRU defined LET_{Δ} as the restricted stopping power where the upper limit of integration is set to Δ (ICRU, 2011). Fig. 24 illustrates the Bragg peak associated an LET plot (Sgouros et al., 2010). It has essentially the same shape as the plot in Fig. 22 for stopping power.

Fig. 24 LET as a function of penetration depth in water for alpha particles of two energies. Alpha particles with lower initial kinetic energy travel a shorter distance before depositing energy in their Bragg peaks, resulting in higher LET. At the bottom of the plot, electrons with initial kinetic energy of 100–500 keV are shown for comparison. Reproduced from Sgouros G, Roeske JC, Mcdevitt MR, Palm S, Allen BJ, Fisher DR, Brill AB, Song H, Howell RW and Akabani G (2010) MIRD Pamphlet No. 22 (abridged): Radiobiology and dosimetry of α -particle emitters for targeted radionuclide therapy. *Journal of Nuclear Medicine* 51: 311–328.

Conclusion

Interactions of radiation with matter in health physics and radiation protection all stem from fundamental physical interactions at the atomic and subatomic levels for target media of interest including tissue, shielding materials, and radiation detectors. By understanding the fundamental mechanisms of energy transfer via radioactive interactions yielding energetic particles (protons, alpha, beta, neutron, etc.) and waves (X-rays, gamma rays) relevant to health physics, we can use these fundamental quantities to measure radiation fields and correlate these quantities with regulatory standards of these interactions.

Naturally occurring radioactive isotopes

There is a general scientific consensus that all elements were created by the “Big Bang,” followed by subsequent transmutations that took place in Supernova and in other stellar events. Cosmic clouds of these isotopes presumably condensed into stars, planets, and other objects that are found in our planetary system. Given that the Earth is estimated to be about 4.5 billion years old, only radioactive isotopes that originated with the Big Bang, and have half-lives longer than about 100 million years, can be readily measured with current technology. These are referred to as primordial radionuclides. Radioactive isotopes with relatively long (millions of years) and short (days to thousands of years) half-lives are continually produced by decay of primordial isotopes and by transmutations associated with cosmic radiation. Radioactive isotopes that are continually produced by the interaction of cosmic radiation with the atmosphere and other materials are referred to as cosmogenic.

Naturally Occurring Radioactive Materials (NORM), such as uranium, thorium, radium, radon, carbon-14, beryllium-7, potassium-40, fission products (from spontaneous fission of uranium in NROM), etc. are encountered by humans every day (epa-2). These materials, in conjunction with cosmic radiation, result in doses to humans that range from about 1.5 to 3.5 mSv/year (150 to 350 mrem/year). Surprisingly, the following locations: Guarapari, Brazil; Kerala, India; Ramsar, Iran; and Yangjiang, China, have natural background radiation that are relative high (> 5000 mrem/year or 50 mSv/year) (Sohrabi, 1997, 1998). The activity of 1% uranium ore is 33,000 pCi/g, in soil it ranges from about 0.5 to 5 pCi/g, and the activity in barrels of oil radium concentration has been reported to be 400,000 pCi/g.

Primordial

Primordial and other terrestrial radionuclides contribute about 20 mrem/year from direct external radiation and about 220 mrem/year to lungs due to alpha particles emitted by the decay products of radon (Fig. 1). Because radon is a noble gas, it does not attach to the lungs when inhaled so direct dose contributions are negligible. The mechanism for exposure is through its decay products [primarily Po isotopes]. They attach to dust particles in the air which may be inhaled and remain embedded within the lung for a time that depends on their solubility. Emission of alpha particles by radon decay products, namely polonium, cause essentially all of the dose to lungs.

Illustrations of primordial isotope decay chains are shown in Fig. 2, and lists of decay modes are shown in Tables 1 through 3. Two of these decay chains, U-238 and Th-232, dominate the natural background source term, but the contribution of the U-235 decay chain (which originally started with Pu-239) is also relevant even though its natural abundance is only 0.7% of natural uranium. You may note from Fig. 2 that there are three Po isotopes in the U-238 decay chain, two in Th-232, and one in U-235. Table 1 lists two Po isotopes in the Pu-239/U-235 decay chain, but it has only a 1.78 ms half-life so it is neglected in Fig. 2.

The concentration of U-235 in uranium is only 0.7%, so its contribution to radiation exposure is small relative to that of U-238. Radioisotopes in ore that have not been disturbed for several half-lives of the longest-lived isotope all have the same activity (product of its number density times its decay constant). In particular, the radioactivity of U-238, U-235 and Th-232, decay chain products are effectively in equilibrium after several half-lives of the longest-lived daughter.

Cosmogenic

Interactions of cosmic rays with the atmosphere, earth, sea, etc., result in the production of several radionuclides that are readily measurable. Those of most significance include: H-3, Be-7, C-14, and Na-22. Others are produced by secondary neutrons and by high energy collisions with galactic radiation. These radionuclides contribute about 1 mrem/year to the annual equivalent dose. The reactions that produce these isotopes are as follows:

1. Tritium (H-3 or T) is produced primarily by the reactions: $^{14}\text{N}(\text{n},\text{T})^{12}\text{C}$ and $^{16}\text{O}(\text{n},\text{T})^{14}\text{N}$, and it has a half-life of 12.3 years.
2. The reaction $^{14}\text{N}(\text{n},\text{p})^{14}\text{C}$, accounts for most of the C-14 produced by cosmic radiation. C-14 has a half-life of 5730 years.
3. Be-7 is produced by high energy interactions with nitrogen and oxygen and has a half-life of 53.4 days.
4. Na-22 results from neutron interactions with argon and has a half-life of 2.6 years.

Average Annual Radiation Dose

Technology enhanced naturally occurring radioactive material

The concentration of uranium in commonly encountered soil is about 3 ppm (2 pCi/g or 0.07 Bq/g). However, uranium ore may contain uranium from a fraction of a percent to over 10%. In seawater, uranium has a concentration of about three parts per billion (3 ppb) and generally about 1 ppb in crude oil.

Processes that concentrate NORM to produce Technology Enhanced Naturally Occurring Radioactive Material (TENORM), which are of interest in radiation protection include the following:

1. Mining
2. Hard Rock Metal Mining
3. Rare Earths Mining Wastes
4. Uranium Mining Wastes
5. Copper Mining and Production Wastes
6. Bauxite and Alumina Production Wastes
7. Energy production
8. Oil and Gas Production Wastes
9. Coal Combustion Residuals
10. Water treatment
11. Drinking Water Treatment Residuals
12. Wastewater Treatment Residuals
13. Consumer products
14. Fertilizer and Fertilizer Production Wastes
15. Cigarettes
16. Building Materials
17. Granite Countertops

Each of these processes concentrate NORM in different ways. For example, cigarettes use tobacco plants which accumulate uranium from soil, waste water treatment plants facilitate precipitation of radionuclides in sewage, NORM in crude oil plates out on pipeline and tanker car surfaces, and crushing of ore during milling releases decay products of uranium and thorium which can easily leach into the environment. The concentration of NORM and the pathways for human exposure vary for each of the items above. A detailed 300-page report ([epa-2402-R-08, 2008](#)) provides a thorough assessment of concentration of NORM during mining operations, as well as its health effects.

The Environmental Protection Agency (EPA) has overall regulatory responsibility for TENORM, and it is investigating health-related concerns in following ways:

1. Characterization of residual wastes,
2. Evaluation of potential exposures,
3. Identification of origin of materials,
4. Collaboration with industry, and
5. Collaboration with other regulatory agencies.

Reactor- and accelerator- produced isotopes

Radioisotopes find various uses in modern life, including medicine, industry, agriculture, and research. Although some of these isotopes may occur naturally through the processes described earlier, their concentrations are usually too dilute for use. Hence, they are produced artificially, primarily in research reactors and accelerators. The choice of using a reactor or accelerator in the production of isotopes for medical, industrial, or research use is due in large part to the type of radiation desired. For example, for use in Positron Emission Tomography, isotopes of interest must decay by emitting a positron. Thus, they need to be proton rich, and this is accomplished by irradiating the target material with high-energy protons using an accelerator to cause proton-induced nuclear reactions. On the other hand, if a beta emitter is preferred, isotopes that are neutron rich need to be produced since they decay by beta emission to reach the line of stability. These can be formed as fission products or through neutron irradiation of targets in a reactor. Isotopes that emit alpha particles generally have an atomic number greater than 80. They may be generated in reactors by transmutation of elements or in nature as decay products of NORM. In either case, they are obtained by chemical extraction from source material.

Reactor-produced isotopes

More than 80% of medical imaging for diagnosis of diseases such as cancer makes use of the isotope technetium-99m ($Tc-99m$), which is the decay product of the radioisotope molybdenum-99 ($Mo-99$) which is produced in research reactors.

$Mo-99$ makes up approximately 6.1% of the fission product yield from fission of $U-235$. It has a half-life of 66 h, which requires continuous production and delivery to hospitals. As a result, $Mo-99$ is produced in research reactors through neutron irradiation of high-enriched uranium targets. The targets are exposed to neutrons for several hours followed by chemical processing to isolate the $Mo-99$ produced. In a typical generator used in a medical setting, the $Mo-99$ is preloaded by adsorption onto the surface of aluminum oxide columns. When a saline solution is passed over the column, any produced $Tc-99m$ is preferentially washed away and thus extracted.

As of 2020, the global demand for Mo-99 is provided by the following research reactors:

1. BR-2 reactor at the SCK-CEN in Belgium
2. HFR at Petten in the Netherlands
3. LVR-15 reactor in the Czech Republic
4. MARIA reactor in Poland
5. OPAL reactor in Australia
6. SAFARI-1 reactor in South Africa

Additional information on several of these reactors is available in the following chapters of this encyclopedia:

01006. BR-2 (100 MW) by *Steven Van Dyck*,

01008. High Flux Isotope Reactor (HFIR) by *Tim Powers, David Chandler and Christopher Bryan*,

01014. MARIA (30 MW Poland) by *Michal Gryzinski, and*.

01015. OPAL (20 MW Australia) *David Vittorio*.

Radioisotopes such as I-131 and Xe-133 that are also used for some medical imaging are also important fission products and may be produced at the same facilities.

Some isotopes, such as Co-60, are produced through dedicated neutron irradiation in a reactor. Cobalt-60 (Co-60) is a strong gamma emitter used mainly for sterilization of medical devices and in industrial radiography. It is produced through neutron capture in nuclear reactors. Specially prepared targets of cobalt-59 can be introduced into a flux trap through a dedicated chamber, or in some cases dedicated rods of Co-59 are placed in certain fuel assemblies. The cobalt-59 absorbs a neutron and converts into Co-60 which is processed in hot cells and sealed in tungsten lined containers filled with an inert gas before being shipped off for use.

In the United States, the High Flux Isotope Reactor (HFIR) at Oak Ridge National Laboratory (ORNL) provides one of the world's highest steady-state thermal neutron fluxes (up to 3×10^{15} neutrons $\text{s}^{-1} \text{cm}^{-2}$). It is a light water-cooled reactor that uses high-enriched uranium as fuel. HFIR contains more than 40 target locations within the core and reflector. Products made at this facility include Ni-63, W-188, Re-186, Cf-252, and Ir-192.

A few additional examples of useful reactor-produced radionuclides include the following applications:

Ni-63: Used for detection of explosives in homeland defense initiatives and as a power source for remote instrumentation.

Ga-68: Used as a positron source to calibrate Positron Emission Tomography (PET) scanners that are widely used in medical research and cancer imaging.

W-188: This is the parent isotope of rhenium-188 used to prevent the re-closure (restenosis) of coronary arteries following heart surgery. Also used as a monoclonal antibody label and to relieve bone cancer.

Ir-192: Used in gamma radiography to image the structural integrity of aircraft, pipe welds, ships, bridges, and other structures.

Ac-225: Extracted from Th-229, which is extracted from a unique inventory of U-233 at ORNL. Both Ac-225, and its decay daughter Bi-213, are alpha emitters and have shown considerable promise in the treatment of cancer.

Pu-238: Owing to the high density of plutonium ($< 19 \text{ g/cm}^3$) and half-life of 87.7 years, the strong alpha-emitter Pu-238 is used as a source of heat and energy in radioisotope thermoelectric generator units deployed in rovers and satellites for space missions.

Cf-252: Used to treat cervical cancer. It also undergoes spontaneous fission and is a source of neutrons to start up reactors. Also used to gauge the moisture content of soil at road and building construction sites.

Accelerator produced isotopes

The efficacy of producing specific isotopes may favor use of a reactor or an accelerator. Generally a higher specific activity can be obtained by using charged particles (generated by accelerators) rather than neutrons (generated by reactors) since multiple isotopes of a particular element will be generated by neutron irradiation but not when irradiating with charged particles (usually protons). Other factors that may influence decisions for using neutrons versus protons include the following:

1. Chemical processing requirements following irradiation,
2. Half-life of the isotope of interest,
3. Transportation logistics,
4. Cost of production, and
5. Specific activity.

Discussion of the advantages or disadvantages using neutron, protons, or other charged particles change because of technological capabilities over time and due to regulatory considerations. Some useful accelerator-produced isotopes include the following:

Cd-109: Used to induce X-ray emission in coal and other materials such as metal alloys for quantitative and qualitative analysis. Characteristic X-rays (induced by photons from Cd-109) from sulfur, for example, provide information on sulfur content of coal and lead to cleaner burning coals.

Si-32: Used as a radioactive tracer to measure silicon uptake by oceanic phytoplankton and thereby monitor possible trends in global warming.

Na-22: Used medically in neurological research and commercially as a radiation source.

Sr-82: As the parent of rubidium-82, it is often sold as a generator. Rubidium is a chemical analog of potassium which makes it ideal for cardiac imaging.

Several high-energy accelerator facilities and their characteristics are identified below.

Los Alamos Neutron Science Center (LANSCE)

The Los Alamos Neutron Science Center (LANSCE) at LANL is a half-mile-long accelerator that delivers 800 MeV protons, at up to 1 mA of H⁺ and 100 microamperes of H⁻.

The unique characteristics of the LANSCE accelerator include a high-energy, high-beam current that allows production of higher quality radioisotopes as well as radioisotopes that cannot be produced in other facilities. The site's three major products are Ge-68, Sr-82, and Na-22.

Isotope production facility (IPF)

The isotope production facility (IPF) is a 100 MeV proton bombardment station located at LANSCE. The facility can produce high current beams for large scale production of radioisotopes as well as delicate low current beams for experiments. IPF also maintains a robust hot cell facility for processing and handling of targets used in radioisotope production. Thus, the isotope program at LANSCE produces radioisotopes that are in short supply utilizing the unique capabilities of the facility.

The program produces Sr-82 generators for critical cardiac imaging and Ge-68 used for diagnostic procedures. The IPF is also gearing up to increase the availability of Ac-225 for targeted alpha therapy. Other isotopes produced include high purity Na-22 for positron emission tomography, As-73 for environmental research, and ³²Si as a tracer for groundwater discharge.

Brookhaven Linac Isotope Producer (BLIP)

The Brookhaven Linac Isotope Producer (BLIP) at BNL utilizes the excess beam of a linear accelerator that injects 200 MeV protons into the 33 G electron-Volt Alternating Gradient Synchrotron. The BLIP facility produces such radioisotopes as strontium-82, germanium-68, Tc-95m, Cu-67, and Be-7.

Research, medical, and industrial applications

Radioactive materials often have sufficient activity that remote processing and handling is required to avoid excessive exposure to personnel. The Department of Energy (DOE), institutions, and other industries have developed handling, processing, and measurement facilities and capabilities that make stable and radioactive isotopes available for use.

Isotope Programs

Hot cell facilities: A hot cell is a closed work area in which radioactive materials may be manipulated without exposing the operator to gamma radiation. Some cells are dedicated to the production of a single radioisotope in order to minimize contamination. Other cells are used to process a wide range of isotopes while still others are used for storage and transfer functions. They are an integral part of radioactive isotope production and their care and maintenance are high priorities. Isotope Programs make use of hot cell facilities at Oak Ridge National Laboratory (ORNL), Idaho National Laboratory (INL), Los Alamos National Laboratory (LANL), and Brookhaven National Laboratory (BNL).

Byproducts and stockpiled materials: The program obtains isotopes from the processing of byproducts and stored nuclear materials from other DOE programs. For example, Pacific Northwest National Laboratory (PNNL) has produced radio-chemically pure Y-90 by processing Sr-90, a byproduct of nuclear fission reactions. Researchers throughout the United States are now using Y-90 in treating Hodgkin's disease and other types of cancers. PNNL has a large stock of partially purified Sr-90 and some which have been completely purified.

Highly fissile U-233 has been processed by DOE to extract Th-229, the parent radioisotope of Ac-225 and other alpha emitters that show promise as cancer therapeutics. Other stockpiled materials that could be processed for sale include Cs-137, Ac-227, U-232, C-241, Am-243, Cm-244, and a small amount of Ra-226.

Calibration, research and radiography

Effective radiation protection makes use of various instruments that detect and measure the radiation present in the environment. These devices come in different sizes, with some being portable. Regulations require that such radiation detection instruments must be routinely calibrated against known radiation sources. For example, all portable count rate meters (commonly known as "Geiger" counters) and exposure rate meters (commonly referred to as ion chambers) require annual calibration. Co-60 and Cs-137 are generally used for calibration given their relatively long half-lives (few years) and the high energy gamma rays that they produce. Disposal of such sources could pose a health risk. Uncontrolled disposal of Co-60 with scrap metal has been responsible for radioactivity found in various steel and iron-based products (NRC IN-83-16, 1983). In one instance, the company Petco had to recall

several models of steel pet food bowls in August 2012 after it was determined that they were emitting low levels of radiation. The source of the radiation was determined to be Co-60 that had contaminated the steel.

In another incident in Ukraine, a Cs-137 source used for detector calibration was lost in a quarry. Eventually, the gravel from the quarry was used in the construction of an apartment building. Several residents had been exposed to high levels of radiation which tragically led to six deaths.

Research activities in various fields make use of radioactive materials. For example, researchers in the field of radiopharmaceuticals use radioactive materials as “tracers” to develop new medicines and test their effectiveness. To do this, some researchers use specialized detectors called “tracers” that track how material travels through a person or animal. In a radioactive tracer, the researcher replaces some atoms of the medicinal compound with a radionuclide. The radiation from the isotope can be used to study the biokinetic chemical interactions that the medicine undergoes within the body. Positron emitters such as carbon-11, nitrogen-13, and fluorine-18 are generally used as tracers in radiopharmaceutical research. Agricultural researchers use similar type of tracers to track the movement of certain materials through plants. Tritium (H-3) and C-14 are commonly used to study metabolism.

An imaging technique called radiography makes use of X-rays, gamma rays, and other radiation to image the internals of an object. Common radiographical techniques include X-ray imaging and computed tomography (CT) scanning in medicine. In industrial application, radiography is used as a method of non-destructive examination to verify the integrity of the product. Commonly used sources include Co-60, Sr-90, K-85, Cs-137, Ir-192, and Yb-169.

Radioactive sources also find uses in hydraulic fracturing (fracking) to determine injection profile and location of created fractures. Tracers with different half-lives are employed in the different stages. According to the NRC, common tracers include Sc-46, Br-82, Sb-124, I-125, I-131, and Ir-192.

Nuclear fuel cycle

Natural uranium may be used as reactor fuel to sustain a chain reaction if it is combined with materials that have very low neutron absorption cross sections and effectively reduce neutron energies to thermal equilibrium with their environment. There is evidence that a sustained chain reaction occurred naturally in Africa about 2×10^9 years ago. Since the half-life of U-235 (7.04×10^8 years) is significantly shorter than that of U-238 (4.48×10^9 years), the natural abundance of U-235 has decreased from about 4% at that time to a value of 0.71% today. Most commercial vendors of nuclear reactors use U-235 as the fissile isotope for sustaining the chain reaction for Light-Water Reactors (LWRs), where the enrichment of U-235 is about 4%–5%. One exception is the CANDU (Canadian Deuterium-Uranium) reactor, which uses water with deuterium (heavy water) in place of light water (ordinary water) to moderate the neutron energy and natural uranium fuel. Other designs have used high purity graphite with natural uranium to obtain a sustained chain reaction.

Uranium is mined and converted into chemical and physical forms that are suitable for production of energy by fission, and these activities require an extensive industrial infrastructure. Variations in reactor types that use different types of fuel (and alternative methods for utilization of energy produced by fission reactions) result in many corresponding variations on the facilities and materials required to support particular methods for utilization of nuclear energy. Thousands of reports and technical papers have been written to evaluate configurations of infrastructure and reactor types that support the sustainable use and safe use of nuclear energy. An illustration of a generic fuel cycle is provided by Fig. 3, and approximate material flows are shown in Fig. 4.

In order to produce electricity by fission of uranium or plutonium, several distinct processes are required. For the once-through fuel cycle practiced today in the United States, the following are required:

1. Mining and milling,
2. Chemical conversion,
3. Enrichment,
4. Fuel fabrication, and
5. Storage or disposal of used nuclear fuel.

For many LWRs, the initial enrichment of U-235 is 5% or less, and the remainder is about 95% U-238. During the 3–5 years of residence time in the reactor several percent of the U-238 is converted to Pu-239. Roughly one-third of the energy produced by the fuel is due to fission of Pu-239, and approximately one-half of the reactor power is being produced by Pu-239 near the end the fuel's residence time in the reactor. In order to utilize the energy potential of used nuclear fuel (UNF) more effectively than with the once-through fuel cycle, fuel reprocessing and recycling is required as is the practice in France. It is important to notice that each of these processes result in exposure to radiation that requires unique protocols for radiation protection. All facilities are operated to comply with established regulations; consequently, radiation exposures are held below levels that are of health-related concerns.

Each activity separately identified in Fig. 5 (Credits-1, n.d.) has the potential for releasing radioactivity of different isotopes and of different chemical composition to the environment. For example, surface and underground mining results in crushing uranium ore, and this, in turn, permits primordial radioactive isotopes to easily migrate. Potential releases from the most significant activities shown in Fig. 5 are described below.

The Nuclear Fuel Cycle

* Reprocessing of spent nuclear fuel, including mixed-oxide (MOX) fuel, is not practiced in the United States.
Note: The NRC has no regulatory role in mining uranium.

As of January 2019

Fig. 3 General illustration of the Nuclear Fuel Cycle.

Mining and milling

Mining of uranium may be accomplished by surface mining, pit mining, and by leaching. Although the radioisotopes in the ore are the same, exposure pathways are very different for each of these methods of mining. For the case of surface mining, radon, and its decay products should be of significantly less concern than for the case of pit mining when personnel are directly exposed to contaminated air. Underground mines, from about 1950 through 1970, were not well ventilated, and as a result, miners received sufficient dose from radon decay products that, based on probability of causation analyses, developed cancer from their work in uranium mines.

Note from **Tables 1–3** that there are many isotopes that are initially in secular equilibrium with U-238, U-235 or Th-232 when the ore is mined. The decay chains listed in these tables collectively produce seven polonium isotopes below Radon. They are alpha emitters and are of primary concern for exposure to radiation from mill tailings. These polonium isotopes, Po-211, 215, 210, 214, 218, 212, and 216, attach to dust particles in air, and about 30% (depending on particle size) of the intake is retained in the lungs after they are inhaled.

During early mining and milling activities (1960–80), about 30 separate mining locations were in operation, and mill tailings were accumulated in piles near the location. Radioactivity in the crushed rock was, at that time, considered to be as hazardous as spent fuel, and this led to the passage of the Uranium Mill Tailings Radiation Control Act (UMTRA) of 1978 (Public Law 95-604). As

a result, to date (2020), these locations are remediated as required by regulations and are not considered to present any significant radiological hazards to the public. Various methods for mining and milling are illustrated in Fig. 5. Radiation exposure results from inhalation and direct radiation of NORM.

Conversion

The chemical form of uranium after milling is primarily U_3O_8 and is often referred to as “yellow cake,” which is converted to uranium hexafluoride (UF_6) for enrichment. At this stage of the fuel cycle, the isotopes below U in the decay chain are essentially not present. Thus, uranium is the radioactive isotope of concern for radiological-related health issues during conversion processes.

Enrichment

Light Water Reactors (LWRs) require the concentration of the fissile isotope (U-235) in natural uranium to be increased well above its natural abundance (0.7%) in order for them to sustain chain reactions. Uranium is the radioactive isotope of concern for radiological-related health issues.

Changing the relative concentrations of a particular isotope in an element can be accomplished through the use of selective migration of one isotope versus another. Some of the basic physics differences that may be utilized to accomplish separation include the following:

- atomic absorption spectra,
- momentum,

- mass, and
- molecular size

The process of increasing the fraction of U-235 relative to U-238 in uranium (enrichment) results in radioactive source terms through the following pathways:

- loss of material that becomes airborne,
- loss of material that plates out on surfaces, and
- concentration of trace radioactive elements.

Fuel fabrication

Commercial fuel fabrication plants in operation in the USA are located at Richland, WA (Framatome), Columbia, SC (Westinghouse), and Wilmington, NC (General Electric (GNF-A)). Fuel fabrication plants that support the Department of Energy are located at Lynchburg, VA and at Erwin, TN. These facilities release naturally occurring radioactive material (primordial) in very small quantities; consequently, they pose minimal radiological hazards to the environment and to humans.

Reactors

There are about 400 nuclear fission power reactors in operation (CE 2020) that use water for coolant and for moderating the neutron spectrum to a near thermal equilibrium with the reactor moderator. These reactors are generally classified as Light Water Reactors (LWRs) and are further characterized as Pressurized Water Reactors (PWRs) and Boiling Water Reactors (BWRs). Some other reactor designs of significant interest include:

- Heavy-water reactors
- gas for coolant and graphite for moderation,
- sodium cooled,
- molten salt reactors with fuel dissolved in the salt,
- molten salt cooled, and
- lead cooled.

The production of fission products per unit of energy production is within a few percent, regardless of the reactor type. In particular, they produce about one ton of fission products per giga-watt-year of energy production. The thermal spectrum, low enriched uranium fueled, reactors produce about 200 kg of Pu-239 (and other transuranic isotopes) and about 1000 kg of fission products per giga-watt-year of energy production. However, the mass of transuranic isotopes produced varies significantly, depending on the reactor neutron spectrum, fuel cycle type and enrichment of the fissile isotope. The transuranic isotopes typically have half-lives of thousands of years and therefore present the primary concern for radiation exposure many generations in the future.

During normal operation commercial LWRs release radioactivity in gaseous, liquid, and solid forms. The United States Nuclear Regulatory Commission (USNRC) is responsible for assuring compliance with protocols defined in the licensee's permission to operate these facilities. Measurements are required at the points of release, and dosimetry external to these plants is periodically monitored. Shipments of radioactive materials to offsite locations is regulated by the Department of Transportation, the Environmental Protection Agency, and by Waste Acceptance Criteria (WAC) established by the receiving organization.

During the past 50 years of LWR operation the activity of radioactive waste produced per unit of energy generated (excluding fission products and transmuted isotopes) has decreased by about a factor of 100 for Boiling Water Reactors (BWRs) and by about a factor of 10 for LWRs (Till and Grogan, 2008).

Used nuclear fuel

Irradiated nuclear fuel is stored inside the reactor containment building associated with the reactor and is moved to temporary storage when extra storage capacity is needed. Fig. 6 (Credits-2, n.d.) illustrates some options for handling, storing, and disposing of used nuclear fuel.

Reprocessing

When nuclear power plants were first being built in the 1960s and 1970s, there was a general consensus that used nuclear fuel from LWRs would be reprocessed and that the plutonium transmuted from uranium would be extracted and used to start sodium-cooled fast breeder reactors. One commercial reprocessing plant was built at West Valley, New York, and operated from 1966 to 1972, and remediation was completed in 2002 under the West Valley Demonstration Project (WVDP) with a cost of about \$5 billion. Another commercial reprocessing plant, the Barnwell Nuclear Fuel Plant (BNFP) was built in Barnwell, South Carolina, but it was not placed into operation due to regulatory changes after construction and due to changes in federal policy in 1977. Various studies have shown that the once-through nuclear fuel cycle for LWRs is more economical than one that involves reprocessing and mixed oxide (MOX) fuel

Fig. 6 Options for Handling and Storage of Used Nuclear Fuel. Credits-2. (n.d.) Credits: Left—Perry Nuclear Power Plant, FirstEnergy Nuclear Operating Co., Middle—U.S. Nuclear Regulatory Commission, Right—U.S. Department of Energy.

fabrication for use in either LWR or sodium-cooled reactors. In the long term, when transmuted actinides are considered, reuse of used nuclear fuel may be more economical. Nuclear fuel reprocessing plants are in operation in France and in the Russian Federation.

The Department of Energy has operated nuclear fuel reprocessing plants (for military applications) at the Idaho National Laboratory (INL), the Hanford Site and Savannah River Site. Acidic liquid waste from the first extraction columns (the High Level Waste (HLW) stream) at the Hanford Site and Savannah River National Laboratory (SRNL) is stored in stainless steel tanks, and the pH was subsequently adjusted with a caustic liquid. Thirty-five million gallons of HLW are stored in 43 tanks at the Savannah River Site and 56 million gallons are stored in 177 tanks at the Hanford Site. The HLW liquid at Idaho National Laboratory (INL) was converted to a solid by calcining it to be thermodynamically stable.

Some of the single-walled tanks at the Hanford Site have leaked and some detectable levels of radioactive material has migrated to the Columbia River. No significant leaks are noted to have been reported for the Savannah River site nor at INL. Results from a Radiological Assessment (Till and Grogan, 2008) for the Hanford Site show minimal health impacts to the nearby residence.

Reprocessing of used nuclear fuel (UNF) in the USA has resulted in large expenditures for remediation, and some publications claim that reprocessing is more costly than direct disposal of UNF. Tables 00702-1 and 00702-2 list international locations where reprocessing capabilities of both UO₂ and Mixed Oxide (MOX) exist (Tables 4 and 5). However, the only commercially significant location is in France at LaHague since other locations have either been shut down or have relatively small capacities. Fig. 7 is a photo of the storage facility for vitrified HLW at LaHague in France.

Disposal of radioactive materials

The method for disposing of radioactive materials generally depends on its potential for exposing the environment to radiation, which depends on considerations of radiotoxicity, mobility and half-life. The United States Nuclear Regulatory Commission (USNRC) classifies Low Level Radioactive Waste (LLRW) A, B, C and greater than Class C. This classification scheme is described in 10CFR61.55, and it is based on criteria, such as: toxicity, half-life, and mobility of specific and general radionuclides. Regulations for disposal and transport differ for each class. Materials classified as greater than Class C may not be disposed of by surface land burial.

To date, commercial generators of LLRW may ship to four locations, depending on its classification and on the location of origin. The four active, licensed low-level waste disposal facilities are located in Agreement States and are illustrated in Fig. 8 and listed below. Additional information about the facilities may be found at the Web sites maintained by the respective Agreement States.

- EnergySolutions Barnwell Operations, located in Barnwell, South Carolina: Currently, Barnwell accepts waste from the Atlantic compact states (Connecticut, New Jersey, and South Carolina). Barnwell is licensed by the State of South Carolina to dispose of Class A, B, and C waste.
- U.S. Ecology, located in Richland, Washington: Richland accepts waste from the Northwest and Rocky Mountain compacts. Richland is licensed by the State of Washington to dispose of Class A, B, and C waste.
- EnergySolutions Clive Operations, located in Clive, Utah: Clive accepts waste from all regions of the United States. Clive is licensed by the State of Utah for Class A waste only.

Fig. 8 Low Level Waste Acceptance Sites.

- Waste Control Specialists (WCS), LLC, located near Andrews, Texas: WCS accepts waste from the Texas Compact generators and outside generators with permission from the Compact. WCS is licensed by the State of Texas to dispose of Class A, B, and C waste.

The Low-Level Radioactive Waste Policy Act of 1985 made States responsible for managing the radioactive material generated under licenses that they generated. Since radioactive waste disposal sites in each state is not necessary, various states joined to form “compacts” so they could collectively disposal of radioactive waste at a single site.

Exposure from medical treatment and diagnostics

Radiation exposures in the medical field are of concern for patients, health care workers and members of the public. The field of medicine uses radiation in a number of different ways to diagnose and treat a variety of conditions. Diagnostic imaging which utilizes x-ray machines, Positron Emission Tomography (PET) scanners, Computed Tomography (CT) scanners as well as nuclear medicine imaging have a potential for significant doses to patients as well as incidental exposures to healthcare workers. The field of radiation oncology utilizes high energy linear accelerators to treat cancer. In addition, special treatment units such as gamma knife use gamma rays from Co-60 to treat brain tumors whereas the similar cyberknife uses an accelerator on a robotic arm to treat a variety of tumors including extracranial cancers. These highly specialized devices are effective at treating complex cancers but have a significant risk for patient mistreatments. Radioactive material is also used to treat other cancers. Treatment can either be LDR (Low Dose Rate) or HDR (High Dose Rate). The use of LDR therapy is most often associated with prostate cancer treatment. High Dose Rate therapy is becoming the standard of care in radiation therapy and can treat a wide array of cancers throughout the body. Additional information is available in the following chapters of this encyclopedia.

Introduction

Radiation exposures in the medical field are not limited to patients; healthcare workers as well as members of the public must be considered. Sources of exposure are most often related to diagnostic or therapeutic uses of X-rays. Although X-rays are the most common source of radiation, radioactive materials are also widely used in the field of medicine.

Patient exposures are necessary in order to obtain information to diagnosis many medical problems and to treat cancer, while at the same time, reducing dose to the patient is critical in order to minimize risks for secondary cancers. Dose is only one consideration. Image quality must be excellent in order to reduce the need for repeating studies, which increases doses, but high-quality images allow the practitioner to more accurately diagnose the patient. Thus, optimization of shielding may be utilized to reduce dose to workers as well as members of the public. Newer types of scanners that have entered the marketplace have driven the need for improved shielding.

The field of radiation oncology utilizes X-rays with energies above several MeV and thus requires significant attention to the configuration of the radiation dose. Patient exposures are comprised of the prescribed treatment dose as well as scattered radiation. Healthcare workers and members of the public generally have much less exposure due to excellent shielding of accelerator vaults, which must consider all areas near the linear accelerator.

Radiation therapy also utilizes radioactive material to treat a variety of cancers, known as brachytherapy. These treatments can be either LDR or HDR. Both techniques are very effective but take different approaches from dose rate to isotope. A highly specialized form of cancer treatment is gamma knife. This system utilizes small Co-60 sources to treat brain tumors.

Nuclear Medicine is a specialty area in diagnostic imaging and radiation therapy. For diagnostic studies, patients are injected with radioisotopes and monitored with a gamma camera. The gamma emission of the isotope is captured in the camera. Patients receive dose from the injection, while workers receive incidental dose from the patient and handling of the radioactive material. Another aspect of nuclear medicine involves therapeutic doses to kill cancer cells. Thyroid cancer is the most commonly treated with I-131. This procedure can be done on an outpatient basis, which creates potential issues with exposure to members of the public.

Diagnostic imaging

The largest source of radiation exposure in the medical field is X-ray imaging. Millions of people annually receive a variety of X-ray exams for various conditions. The medical field has developed complex devices and enhanced techniques in order to improve image quality. This improved image quality has led to a reduction in patient dose. Current day CT scanners will deliver a dose of approximately 20 mSv for an abdominal scan. This is a relatively low dose, but proper shielding is required in order to minimize dose to medical workers. For example, CT scanners used to operate as single slice scanners, i.e., a single row of detectors. Modern CT scanners, shown in Fig. 9, are now capable of having multiple rows of detectors and thus increasing their ability to collect additional data per scan. This data can provide dynamic imaging of organs as well reduce scanning times. These systems have an increase in scatter radiation that must be taken into account when shielding is placed and scanner is operated.

Diagnostic imaging is critical in vascular and cardiac procedures. Cardiac catheterization and various vascular studies require significant "beam on" time and a larger field in order to accurately locate and treat the area of arterial blockage. A dose of 8–10 mSv is common during a standard procedure cardiac catheterization. Higher doses are possible if the case is complex. There is a risk to the patient in such instances due to the high skin dose. Patients are advised of this prior to the procedure and must be

Fig. 9 CT scanner. Courtesy of Canon Medical Systems, USA.

monitored for skin erythema post procedure. Physicians and technologists are also at a higher risk due to scattered radiation. Proper use of As Low As Reasonable Achievable (ALARA) techniques is critical to reduce dose. A typical cardiac lab can be seen in Fig. 10.

PET scanners provide a unique challenge in radiation shielding. Newer PET systems frequently incorporate a multi slice CT scanner, shown below in Fig. 11. This adds a significant improvement in functionality in that patients can now obtain two scans during the same procedure. In addition, the scans are fused which lead to increased accuracy of results. Patients receiving a PET scan often receive an injection of F-18, with a half-life of approximately 110 min. The positron emission of 511 keV gammas provides a unique challenge in shielding. Additional lead shielding is required as compared to a standard CT installation. A hot lab is also required in order to store the F-18 isotope. Safety precautions need to be established in order to minimize dose to patients and staff. Healthcare workers are required to receive no more than 5 rem annually.

Fig. 10 Cath lab. Courtesy of GE Healthcare.

Fig. 11 PET scanner. Courtesy GE Healthcare.

Radiation therapy

Radiation therapy also uses X-rays, but at much higher energies. Diagnostic X-rays are generally in an energy range of 30–130 kV. Radiation therapy accelerators produce X-rays in the energy range of 2–23 MV. The radiation therapy treatment beam penetrates deep within tissue, while sparing the skin surface. The percent depth dose can be seen in Fig. 12. The maximum dose occurs below the skin surface. Electron therapy is also utilized for superficial tumors. Electron energies range from 4–20 MeV. The radiation beam is highly targeted in order to reduce dose to normal tissue. The patient inherently receives a large scatter dose depending on the type of treatment regimen that is prescribed.

The primary concern in radiation therapy is radiation exposure to workers as well as members of the public. Accelerator vault design is critical in order to reduce doses to within State and Federal limits. Types of treatments, workload, occupancy factor and use factor are just some of the considerations when calculating primary and secondary barrier thickness.

The use of radioactive materials (brachytherapy) to treat cancer is also common in radiation therapy. Low-dose rate (LDR) procedures are commonly used to treat prostate cancer. LDR therapy is defined as delivering a small amount of gamma radiation dose over an extended period of time. For prostate cancer, I-125 or Pd-103 seeds are inserted into the prostate gland. The dose delivery time can range from 170–600 days, with a prescribed dose to the prostate between 110–144 Gy, depending on the cancer and isotope. Radiation risk to patients and members of the public is very small. The seeds are permanent.

High dose rate (HDR) therapy uses Ir-192 to treat cancers throughout the body. This type of therapy delivers a high dose of gamma radiation in a short period of time. Patient treatment times last from 1 to 20 min, while utilizing a 10 Ci source of Ir-192. Catheters are placed within the patient for treatment delivery. The Ir-192 source travels to preset positions for a calculated amount of time. Due to the high dose rate and energy of the Ir-192 source, shielding is required. Many HDR treatments are performed in accelerator vaults. Some facilities have specialized rooms that are shielded specifically for the average gamma energy of 0.38 MeV. HDR therapy has a number of benefits including rapid delivery, better radiobiological effect on certain tumors and hypo fractionated treatment regimens. A typical HDR unit is shown in Fig. 13.

Due to Ir-192 having a 74 day half-life, source exchanges are generally done every 3–4 months. The required handling of incoming sources as well as shipping back the depleted sources, presents increased exposure risks for the medical physicist as well as the service engineer. State and Federal guidelines require strict controls and processes for these exchanges. Some State agencies will actually be onsite for exchanges to validate proper handling.

Radiation exposures with HDR treatments are potentially more impactful. Emergency situations during treatment delivery require detailed policies on how to handle their radioactive sources safely. Previous incidents have occurred that have resulted in patient deaths as well as severe radiation injuries to healthcare workers due to poorly implemented programs.

Gamma knife is a highly specialized treatment system for brain tumors. Unlike accelerators, a gamma knife (Fig. 14) uses radioactive material for treating patients. A total of 192 Co-60 sources are loaded into the system to deliver dose with submillimeter accuracy. Co is an ideal isotope for brain treatments due to its gamma energies of 1.17 and 1.33 MeV along with a 5.27 year half-life.

Exposure concerns are significant. Unlike accelerators where the machine can be “turned off,” the gamma knife has a constant exposure concern with the Co sources. Medical physicists and radiation therapists have the greatest risk for exposure. Source exchanges, which are done within 5 years require extra caution as sources are removed and new sources are inserted.

Nuclear medicine

Nuclear Medicine is subset of both diagnostic imaging and radiation therapy. Patients receive radioactive material injections to diagnose various conditions. The most common injection is Tc-99m (a metastable state of Tc-99). This radioactive isotope has a half-life of 6 h and does not remain in the body for an extended period of time as well. The gamma emission of Tc-99m is 140.5 keV, which is ideal to be detected using gamma cameras. A typical gamma camera is shown in Fig. 15. Patients need to exercise caution after

Fig. 12 Percent depth dose curves for various collimator settings.

Fig. 13 HDR Unit. Courtesy of Varian Medical.

Fig. 14 Gamma knife. Courtesy of Elekta.

leaving a nuclear medicine procedure since the Tc-99m is still in their system. Excretion of technetium is largely gastrointestinal and renal though the physiology is complex. Nuclear medicine technologists are at an increased risk for exposure due to the number of patients that are seen on a regular basis. ALARA practices are strictly enforced in medical facilities.

Nuclear medicine is primarily used as a diagnostic tool. However, it can include therapeutic treatments. The most common treatment is thyroid cancer. Patients are given a pill containing up to 300 mCi of I-131 where the dosage may be more or less for different patients, based on medical evaluation. The patient is able to leave the hospital and return home in isolation in most cases. This type of treatment presents significant risk to members of the public. The body fluid of patients is radioactive during the treatment. The majority of the I-131 is absorbed by the thyroid within 2 days. The isotope is primarily excreted through the urine. Home isolation is critical during the therapy in order to minimize public exposure. There have been documented cases where patients received the I-131 therapy and returned to work the same day. These instances pose significant radiation risk to members of the public.

Nuclear weapons testing

The first test of a nuclear device, named Trinity, took place in New Mexico, United States in July 1945, as a culmination of the Manhattan Project and the U.S. World War II efforts (Simon et al., 2006, 2020). It was followed a few weeks later by the bombings of the cities of Hiroshima and Nagasaki, in Japan. Nuclear weapons testing continued for much of the 20th century, with atmospheric detonations being carried out mainly by the United States and former Soviet Union, followed by United Kingdom, France, and China. It is now understood that radioactive fallout debris from these nuclear detonations deposited across the entire Earth, being detected in soil, water, foods, even polar ice, and creating exposure conditions via inhalation, ingestion and external irradiation, for people of all ages, ethnicities and locations.

Historical background

The United States was the only country with operational nuclear weapons until 1949, when the former Soviet Union detonated their first device in Semipalatinsk (now part of Kazakhstan). The United Kingdom started testing shortly after, in 1953. Numerous tests were carried out until 1958, when they were suspended through a voluntary moratorium that lasted until September 1961. Extensive testing took place again in 1961 and 1962, but negotiations between the United States and the former Soviet Union led to the Limited Test Ban Treaty, signed on April 5, 1963, which prohibited all nuclear tests except if conducted underground, to ensure little or no releases of radioactivity. However, atmospheric nuclear tests carried out by France and China, who did not sign the Limited Test Ban Treaty, continued until 1980. India, Pakistan and North Korea started carrying out nuclear testing recently, but none of their tests involved atmospheric detonations (Bouville, 2020). A Comprehensive Test Ban Treaty, banning nuclear weapons test detonations in any environment was adopted by the United Nations General Assembly in 1996, but it is not in full force at this time because a few countries have not ratified the document. Nevertheless, constant efforts have been made by most governments to limit the number of nuclear weapons and the number of countries who possess them. From 1945 to 1980, over 500 nuclear devices were exploded in the atmosphere at 13 primary nuclear testing sites around the world, with an equivalent explosive power ranging from 1 kt to 50 megatons of TNT per device and a total power of 440 megatons (Simon et al., 2006; Bouville, 2020).

Characteristics of radioactive releases

Nuclear weapons generated about 150 radionuclides that were released into the environment, many having short half-lives. Out of these about 20 radionuclides are of radiological importance. These radionuclides can be divided into three types:

- Fission products and their decay products (^{131}I , ^{133}I , $^{132}\text{Te-I}$, ^{90}Sr , ^{137}Cs , $^{140}\text{Ba-La}$, ^{141}Ce , ^{103}Ru , ^{106}Ru , ^{89}Sr , ^{91}Y , $^{95}\text{Zr-Nb}$, ^{144}Ce , ^{125}Sb)

- Neutron activation products and actinides (^{54}Mn , ^{55}Fe , ^{14}C , ^{239}Np)
- Leftover fuel material (^{239}Pu , ^{240}Pu , ^{241}Pu , ^3H)

Weapons testing took place in remote locations, at least 100 km from populated areas (continental deserts, isolated islands in oceans), to minimize potential exposures. Depending on the yield and location of an atmospheric detonation (altitude and latitude) radionuclides were injected into the troposphere (the atmospheric layer closer to ground) or higher into the different layers of the stratosphere. Radionuclides in the stratosphere were diffused mainly over the latitude band in which they were injected, with some exchange between hemispheres, and they slowly deposited to the Earth's surface in a matter of months and years. Radionuclides in the troposphere were carried by prevailing winds and circled the Earth for 2–3 weeks within the same hemisphere, before being deposited on the ground. Deposition of radionuclides occurred by settling of particles (dry deposition) or by wet processes (rain, snow, fog). Fractions of radioactive fallout were deposited locally (50–500 km from ground zero) or regionally (several thousand kilometers downwind), with the remainder (global) fallout being dispersed throughout the world.

The activity of radionuclides released from nuclear weapons tests were much larger than the activities resulting from nuclear reactor accidents, such as the Chernobyl accident in 1986. For example, the activities of ^{131}I , ^{137}Cs , and ^{90}Sr released from all atmospheric tests were greater than releases from the Chernobyl accident by factors 400, 10, and 60, respectively (Bouville, 2020). Given that radionuclides lingered in the atmosphere anywhere from several weeks to several years, the activity of short-lived radionuclides decreased significantly before deposition. As such, less than 1% (5300 PBq) of the estimated activity of ^{131}I released globally (675,000 PBq; half-life = 8 days) was deposited onto the ground, while close to 100% of activities ^{137}Cs (900 PBq; half-life = 30 years), ^{90}Sr (600 PBq; half-life = 29 years), or ^{239}Pu (6.5 PBq; half-life = 24,000 years) were deposited. The long-lived radionuclides changed the global radiation environment on Earth and are now part of the radiation background.

All humans have been exposed to small amounts of radioactivity in fallout from nuclear weapons testing. A substantial number of workers and military personnel involved in preparation of tests, carrying out radiation measurements, and decontamination of test sites were exposed at levels higher than the average member of the public. Radiation doses from fallout are commonly calculated starting with activity concentrations of radionuclides deposited on the ground measured at different locations, augmented by information on expected composition of fallout at those locations (Simon et al., 2004). External gamma emitters in fallout produce a relatively uniform exposure of the entire body, but doses from inhaled or ingested radionuclides can differ significantly among organs. Largest doses from weapons fallouts were delivered to the thyroid gland from ingestion and inhalation of ^{131}I . Historical exposures of members of public around the world depended highly on distance from the nuclear test sites, testing conditions, climate conditions, and dietary and lifestyle habits, with annual effective doses being, in general, in the order of a fraction of a milligray, lower than doses from a single whole-body CT scan. However, significant exposures of some populations did occur, leading to thyroid doses of tens or hundreds of milligrays, for example, in people living in villages near the Semipalatinsk test site in the former Soviet Union (Land et al., 2008) or in children in Washington Co, Utah, or Lincoln Co., Nevada near the Nevada Test Site in the U.S. (Till et al., 1995), while children and adults on Rongelap and Ailinginae atolls in the Marshall Islands received doses in excess of several Grays to the thyroid gland (Simon et al., 2010). Effective doses from fallout can be small compared to effective doses from natural background of radiation, but exposures are non-uniform across the human body, with thyroid gland receiving much larger doses. As such, an additional 49,000 cases of thyroid cancer would be expected to occur among the US population from exposure to radioactive fallout from the atmospheric nuclear weapons tests that were conducted at the Nevada Test Site in the 1950s. In addition, there could be as many as 11,000 deaths from non-thyroid cancers related to fallout from all atmospheric tests that were conducted at all sites in the world, with leukemia making up 10% of this total (Bouville, 2020).

Introduction

An assessment of health effects from a radiological release requires information about the quantity and form of the release. Such a radiological assessment of health risks is interdisciplinary. This is because radioactive sources are transported through the environment in myriad ways, and their uptake in biological systems may lead to resurfacing in different forms. As an example, consider a radioactive source that is released in the form of a smoke plume. It may travel for a few miles with the wind, be deposited onto the soil via rainfall, some of it may end up in groundwater and some may be taken up by grass. Cattle grazing on this grass would ingest this material which will then show up in dairy products consumed by a group of people. It is quite clear that tracking the radioactive material through these systems would require knowledge of a variety of disparate subjects. So it comes as no surprise that the methods used today in radiological assessment evolved within individual sciences and merged gradually over the years. Such assessments may be made for a past release (retrospective), a present-day release, or predictive of a future release (prospective). An illustrative equation to describe the interdisciplinary nature of such an assessment is as follows (Till and Grogan, 2008):

$$Risk = (S \cdot T \cdot E \cdot D \cdot R)_{uvc} \quad (1)$$

where S is the source term; T is the environmental transport factors; E is the exposure factors; D is the conversion to dose; R is the conversion of dose to risk further, u is the uncertainty analysis; v is the validation from prior knowledge; c is the communication of results; p is the stakeholder participation.

In the above equation, the ultimate objective is to decipher the relationship between the “source term” and the potential effects on the environment and human health. In the case of a nuclear installation—be it a reactor, an accelerator, or a processing and handling facility—the types and amounts of radioactive material that are available for release into the environment is known as the *source term*. The nature of the source term will vary depending on the facility and the particulars of the process being considered. It is contingent on the mode of release and affected by parameters including the rate of decay of the nuclides, the magnitude and duration of release, and the physio-chemical characteristics of the radioactive contaminants.

In assessing health effects, it is important to distinguish the radionuclides present in the source as different radiation types since they interact differently with matter based on their physical characteristics. Similarly, the chemical properties of the radioactive material affects the modes of propagation that are accessible to it. This makes some sources relatively harmless while others extremely dangerous to living organisms.

Radioactive releases may be routine in operation or may arise from an abnormal event. In either case, an accurate estimation of the source term includes a description of the quantity and form of radioactive material released and of the location and timeline of the release that occurred. In determining the timeline, the rate of release is an important consideration as it may be intermittent or with a time varying rate. Furthermore, the radioactivity may be released directly into the atmosphere, into groundwater, or the soil. Thus, once the source term has been established for a facility, the migration paths through which the radioactivity disperses will be similar, although their relative importance may vary.

For these reasons, a major requirement in the safety analysis report (SAR) for licensing new nuclear facilities is establishing the source term for all credible accident scenarios and for routine operations. This allows the facility licensee to demonstrate to regulatory bodies that inherent features in the design of the facility contribute to the mitigation of accidents. Thus, licensing of new designs and their sites requires that these features be assessed with enough detail in order to meet scientific requirements for the design and regulations aimed at protecting the general public and alleviating concerns. Additionally, in the unfortunate event of an accident, the source term needs to be confirmed through direct observation of radiation release and transport, and future studies will use the data observed for their estimates.

This article is aimed at presenting readers from a broad variety of backgrounds with an overview of the approaches used in estimating source terms for nuclear reactors and for some regulations governing them. Characteristics of different reactor types are discussed as they apply to determining source terms. Normal operation and accident source terms are discussed. Computer codes used for such studies are mentioned along with examples of the types of source terms arising from different reactor types. Some examples of historical events of significance are discussed and their source terms provided. The goal of this article is to inform the reader about the following:

- (1) the nature of source terms from nuclear reactors,
- (2) the considerations that go into determining these source terms,
- (3) representative source terms from normal operation,
- (4) representative source terms from reactor accidents, and
- (5) reactor accidents, and the radiotoxicity of spent nuclear fuel.

Considerations for estimating source term

The primary objective of radiological risk assessment is to minimize exposure to the public. Thus, assessments are concerned with the potential for transporting emitted radioactivity through air, soil, or water. Such sources are expected to reach the public in trace quantities of parts per million (or billion). Hence, only those components of the source term that are capable of escaping containment in a form that can travel along environmental pathways or be carried by surface contamination are of significant interest. Therefore, when examining source terms, it is important to evaluate the probabilities of escape of certain radionuclides from the containment under both routine operation and accident scenarios. Components of the source term that are of little interest include the following:

- (1) inherently immobile (chemically stable solid),
- (2) rigidly fixed in position,
- (3) of such low activity (long half-lives) that they have negligible contribution to health risks
- (4) are so short-lived that they would decay away before migrating to a target population.

A complete description of the source term requires information about the radioactive material released, its chemical form, and when and where the release occurred. These factors must be described with sufficient accuracy and detail to carry out epidemiological studies on the probable health effects in the exposed public. However, this can prove difficult following a source release given the inherent uncertainties associated with reconstructing doses retrospectively. Hence, it is best practice to estimate the source term using different methods, with redundancy being preferable. There are, in general, three independent methods used in estimating the source term, not all of which may be applicable in every situation. The first is to carry out a scoping study using engineering estimates that provide a preliminary assessment of the magnitude of source release expected for various scenarios. Such a study generally utilizes sophisticated computer codes and may either be purely deterministic, or make use of probabilistic/risk-based assessments, or a combination of the two. The second makes use of historical data from source release events at similar facilities and the radioactive release observed in the environment. And the third data set involves direct sampling of the environment following release.

As shown in the illustrative Eq. (1), the source term is first and most important consideration of radiological risk assessment. Its estimation requires the most resources relative to the other parts of the equation. It is evident that predicting the transport pathways and behavior modes for all important radionuclides poses a significant problem. This is especially difficult for the most volatile components and noble gases. For example, a biologically important radionuclide such as iodine-131 is transported in the environment differently and poses differing degrees of risk depending on whether it was released in an organic or inorganic form (Eichholz, 1977). Here it is important to distinguish the “initial source term” from the “release source terms” as the two may vary substantially. For the latter, a reformulation of the initial source term is carried out with considerations of all likely internal pathways and environmental interactions that may modify the chemical or physical form of a radionuclide.

Historically speaking, an often-neglected aspect of determining source terms has been the inclusion of uncertainty figures. Providing a single value for the source term assigns an exaggerated sense of accuracy to the data that may harm public confidence. Instead, it is best practice to provide a range since, in reality, there may not be reliable data. Alternatively, an upper bound deterministic value may be presented to establish the significance of a particular source. In doing so, the doses and risks calculated are far greater than those expected to occur and thus provide a useful comparison for determining the relative impact of different sources. Finally, the source term should be derived with as many different and independent approaches as feasible. Such redundancy allows for cross-examination of the calculations, strengthens the conviction of the investigators, and increases public confidence in the credibility of the estimation.

If a defensible estimate of the source term cannot be established, credible dose and risk estimations cannot be made. This irreparably hurts public confidence in any assessment of the radiological risks emanating from a facility. This is especially important following an accident when considerable media attention is present and there is popular demand for a credible appraisal of the extent of damage and the risks to public health. Therefore, a meticulous and comprehensive evaluation of the source term is critical in radiological risk assessment and should be carried out prior to licensing, in regular intervals during operation, and following accidental radioactive release to the environment.

Modes of release

A range of human activities release radionuclides into the environment. In the case of nuclear power generation, radioactivity may be released both during routine operation of the facility or when accidents occur. Radioactivity released from routine operation is well below regulatory limits and poses no danger to the public.

The released radionuclides may be in the form of dust particles carried by the air, aerosolized particles, gas or vapor, or dissolved or suspended in water or other liquids. Routine releases of radionuclides during operation occur via discharge into air through filtration systems, and to water bodies via liquid discharge outflows. Spent fuel from the reactor that is either stored onsite and eventually sent to a geologic disposal facility also poses a risk, albeit minimal, of releasing radioactivity into the air or water, or to the soil and then to groundwater. In all cases, it is important to have information about the particle size and chemical form or solubility of the released activity to properly model environmental transport of the radionuclides.

For both routine and accidental release, understanding the accessible modes of release is crucial in determining the downstream consequences of the released radioactivity. The release may occur in several ways depending on the process or the accident that occurred. Radioactivity may be released into the air and carried by the wind to be deposited over a large area. Tritium formed from nuclear processes in the reactor may diffuse out of containment through discontinuities such as welds and joints. Some radionuclides may be released in the form of dust particles that can settle on various surfaces at different distances from the facility depending on the weather conditions. Radionuclides dissolved in water may be released into water bodies through underwater discharge. In the case of accidents such as a loss-of-coolant, fission products may vaporize from the fuel or small particles of the fuel can be dispersed.

The type of discharge into the environment may be continuous (such as tritium) or in batches (volatilized fission products from spent fuel discharge). Nevertheless, source term analysis requires a holistic assessment of all the release modes available for dispersion of radioactivity into the environment.

Postulated initiating events (PIE)

In assessing the source term for accidental release, the first step is to define postulated initiating events (PIE). The PIEs establish the scenarios to be analyzed to predict the amount and types of release. The range of PIEs must cover all credible accident scenarios that could influence the safety basis of the facility. The methodology applied in defining PIEs and their consequences predicts the risk and the safety margin associated with the operation of the facility, and must demonstrate that both are acceptable to the regulatory body. Such an analysis covers all accidents identified as design basis accidents (DBA). In addition, the safety analysis of the reactor must cover beyond-design basis accidents (BDBA) for emergency planning and accident management. While a BDBA is defined as an event whose frequency of occurrence is very low, such an event is still theoretically possible and its consequences may be quite significant. Some DBAs and BDBAs could lead to the release of radionuclides to the environment (the source term). Observed frequency of various initiating events at US nuclear reactors was reported by [Poloski and Marksberry \(1999\)](#) for the US Nuclear Regulatory Commission (NRC).

General features of LWRs, FBRs, GCRs, and MSRs important for source term estimation

Nuclear reactors produce power by converting the heat generated through nuclear fission into electricity by operating a power conversion system. The nuclear fuel is most commonly U-235, although Pu-239 and U-233 can also be used. While the Rankine Cycle, which uses high-pressure steam as the working fluid, is the most widely deployed power conversion system today, a variety of thermodynamic power conversion systems have been proposed.

Nuclear reactors are designed to sustain a fission chain reaction. They can be broadly classified depending on the average speed of the neutrons causing fission. That is, the neutron may either be moderated (thermal) or unmoderated (fast). Several types of reactor designs have been devised. The most commonly deployed reactor design in the world today is the Light-Water Reactor (LWR) which includes Pressurized Water Reactors (PWRs) and Boiling Water Reactors (BWRs). In both designs the liquid water is pressurized to > 100 times atmospheric pressure and serves as both a neutron moderator and coolant for the fuel rods. Another type of thermal reactor that uses heavy water (D_2O) instead of regular water is called the Heavy Water-Moderated Reactor (HWR). An archetype of this design is the Canada Deuterium Uranium Reactor (CANDU) designed and deployed by Canada. Similar reactors are also operated in India. HWRs use similar fuel type as LWR although usually use natural uranium that is discharged at $\sim 1/5$ th the burnup of LWR fuel. Some reactors use pressurized gases such as helium or carbon dioxide as coolants and are called Gas-Cooled Reactors (GCR). These reactors were popular in the United Kingdom in the latter half of the 20th Century but have all been decommissioned. Some advanced designs of GCRs also exist that utilize pebble fuel. Unmoderated or fast reactor designs have the ability to produce more fuel than they consume (breeding). These reactors, called Fast Breeder Reactors (FBR), use liquid metals such as sodium and lead as coolants. Then there is a class of reactors that utilizes fluid fuel in the form of molten salts, called Molten-Salt Reactors (MSR). MSRs can be both moderated or unmoderated. The coolant of both fast reactors and MSRs is at near atmospheric pressure.

LWRs use cylindrical ceramic pellets of uranium oxide as fuel. The pellets are loaded into thin tubes of zirconium alloy which are in turn arranged into assemblies. These assemblies are placed in a grid in the reactor core. As the chain reaction proceeds and fuel

burnup increases, fission products build up within the fuel pellets. Some fission products, especially gases, coalesce into bubbles which can lead to swelling and eventually cracking of the fuel elements. The gases may diffuse out into the gap between the pellet and the zircaloy cladding. These diffused fission products have the highest probability of being released into the environment. They may leak out into the coolant through imperfections in the cladding. Unlike PWRs, in BWRs the water in the core is allowed to boil. The steam thus formed passes through a turbine and condenser and the water returns back to the reactor core. Consequently, radioactive contaminants in the coolant that are confined to the reactor building in a PWR travel through the power conversion system in a BWR and may be released into the environment with any steam release. Furthermore, radioactive noble gases are particularly mobile in a BWR and are released to the environment in greater quantities than PWRs during normal operation, albeit well below regulatory limits.

GCRs are similar to LWRs with the fuel in micro encapsulations within graphite. In the former case, the fuel is encased in graphite for moderation. The pebbles incorporate fuel in the form of tiny spherical particles encapsulated in silicon carbide that are embedded in a graphite matrix. Such TRISO fuel pebbles have been designed to be better at containing fission products than traditional zircaloy-clad fuel pellets. In general, reactors in which the coolant is under high pressure (LWR, CANDU, and GCR) possess potential energy for releasing radioactive material into the environment in case of a reactor accident. This is a major concern and hence these reactors are generally placed in large containment buildings made of steel-reinforced concrete.

In sodium-cooled FBRs, the fuel is typically metallic and bonded to stainless steel cladding using sodium. Similar processes as in LWRs lead to swelling and cracking in FBR fuel. Some fission products may also migrate and dissolve into the sodium bonding. If any fuel pins fail, the gaseous fission products will be released into the coolant sodium along with a fraction of the bonding sodium containing migrated fission products. The molten sodium offers excellent fission product retention and with the lack of pressure, there is little potential for dispersal. However, a major accident scenario in FBRs involves coolant leakage. Liquid sodium reacts violently with air and the moisture in it. Thus, the resulting fire can widely disperse any radioactive materials present in the sodium.

MSRs are a unique reactor design in which molten fluoride or chloride salts contain the dissolved fuel. As burnup proceeds, the fission products formed are retained in the system to various degrees depending on their chemical compatibility with the salt. Some fission products form stable compounds while others remain in their elemental form and “plate out” on various surfaces. Furthermore, volatile fission products simply depart from the liquid fuel and can be captured in a gas treatment system. Such a system possesses its own source term in the case an accident occurs. MSRs operate at just above atmospheric pressure and as a result have little potential for dispersing radioactive fission products as compared to a high-pressure system such as an LWR. Additionally, molten salts are generally non-reactive with air or water, although individual fission products entrained in the salt may react and be dispersed.

All nuclear reactors are designed with radioactive waste management systems to retain as much of the radioactive materials as possible such that the amount that is released into the environment can be described to be “as low as reasonably achievable” (ALARA) and “as low as reasonably practicable” (ALARP). As discussed in [Rempe and Williams \(2021\)](#), attainment of the ALARA objective is of paramount importance in both the designing and operation of nuclear reactors ([U.S. Nuclear Regulatory Commission, 2013](#)).

Important radionuclides in nuclear reactor source terms

Source term estimation for a nuclear reactor facility will include information about several radionuclides of interest. While radionuclides are generally categorized as natural and “man-made,” the differences are not always quite apparent. For example, nuclides such as ^3H and ^{14}C which are formed via nuclear interactions in an operating reactor are also formed through cosmic ray bombardment in the atmosphere ([Sinclair et al., 1987](#)). Although rare, uranium atoms undergo spontaneous fission in nature and the resulting radionuclides are present in trace quantities. Furthermore, geologic studies have found evidence of natural nuclear reactors such as the one in Oklo in the Central African nation of Gabon that existed 2 billion years ago, when the relative $^{235}\text{U}/^{238}\text{U}$ ratio on Earth was greater ([Cowan, 1976](#)).

The naturally occurring isotopes of uranium, ^{235}U and ^{238}U , are most used in nuclear facilities. While these isotopes have long half-lives, their short-lived decay products are important in risk assessment. When used in a nuclear fission reaction, for every fissile atom of ^{235}U consumed, two smaller “fragments” or atoms called fission products are produced. Since the fissile atoms are neutron rich, the fission products produced possess an excess of neutrons which makes them highly radioactive. They shed these excess neutrons, mainly via β^- decay, until the neutron-to-proton ratio is stabilized. Often, these decays are accompanied by gamma rays. Only those fission product combinations are produced that conserve both charge and mass. Hence, the fission product distribution differs with the fissile fuel. [Fig. 1](#) shows the typical fission product yield for ^{233}U , ^{235}U , and ^{239}Pu in a thermal reactor.

PWRs also utilize soluble boron for reactivity control. Boron has a high neutron capture cross-section and undergoes a variety of reactions including $^{10}\text{B}(n,2\alpha)^3\text{H}$ which leads to the contamination of coolant with tritium. Some structural materials may become radioactive through interaction with neutrons through a process called activation. Examples include $^{54}\text{Fe}(n,\gamma)^{55}\text{Fe}$, $^{59}\text{Co}(n,\gamma)^{60}\text{Co}$, $^{58}\text{Ni}(n,p)^{58}\text{Co}$, and $^{56}\text{Fe}(n,t)^{54}\text{Mn}$. An activation product that is important from a radiological risk assessment perspective is ^{134}Cs that is formed by neutron capture of stable fission product ^{133}Cs . While other cesium isotopes are formed as fission products, ^{134}Cs is formed almost exclusively via neutron activation. Thus, the ratio of ^{134}Cs to other isotopes is an indicator of the extent of radioactive contamination from a reactor accident where ^{133}Cs is left in high neutron flux as opposed to nuclear weapons fallout where ^{133}Cs is not ([Perkins et al., 1990](#); [Chino et al., 2016](#)). In FBRs with sodium coolant, neutron capture reaction in ^{23}Na creates ^{24}Na as

Fig. 1 Thermal neutron-induced fission yield for ^{233}U , ^{235}U , and ^{239}Pu per fission. Source: JAEA Nuclear Data Center.

an activation product which has a half-life of 15 h. These fission and activation products form the bulk of the source term in nuclear reactors. **Table 1** presents a list of important radionuclides produced during LWR operation.

Detailed methods for calculating activities of individual radionuclides resulting from fission product decay chains and neutron activation can be found in most textbooks on Nuclear Engineering (Glasstone, 1955; Lamarsh and Baratta, 2001). Similarly, several sources of information exist which present the decay schemes of radionuclides of interest in radiological risk assessment such as the Nuclear Data Services section of the IAEA. Several sophisticated computer codes such as ORIGEN have been created to perform isotopically detailed calculations of the buildup, decay, and release of radionuclides based on reactor operational history (Rearden and Jessee, 2018).

Source terms encountered during normal operation of LWRs

One could believe that nuclear reactors today are like old aging cars resulting in the misleading view that they pose a danger to public wellbeing. After all, a cross country trip in a 1969 Chevy is not very ideal. However, this comparison to old automobiles could not be farther from the truth. While cars remain mostly fixed in their design after exiting the assembly line, operating nuclear power plants undergo a series of improvements during their lifetime resulting from gathered operational data that leads to better operating practices, comprehensive maintenance programs, and several design upgrades. Moreover, there is a continuous improvement in the design of the nuclear fuel that is replaced every few years of reactor operation. The US NRC has implemented a regulatory approach that maximizes safe operation which has resulted in the US nuclear industry achieving one of the best industrial safety records of any other industry (Nuclear Energy Institute, 2020).

Since all power-producing reactors in the United States are presently LWRs, there is long-term data available for their operational source terms. Of the radionuclides listed in **Table 1**, only some are released into the environment during reactor operation, and during reactor spent fuel handling, and storage—all of which are essential to plant operation. Not all the radionuclides are equally important from a health risk perspective and their contribution to the source term varies with the reactor type. To show a representative snapshot, **Table 2** provides normalized amounts of radionuclides released from US power reactors for the year 1988. The amount released by any particular reactor will depend on the type of effluent treatment system employed, the power level, and a mix of other factors.

The radionuclide releases from PWRs and BWRs differ. While the absence of steam generators in a BWR simplifies piping and reactor layout, it also allows radionuclides from the reactor core that are dissolved or suspended in the coolant to travel through the power conversion system and become available for release into the environment. **Fig. 2** shows normalized release rates of noble gases from PWRs and BWRs in the United States. It is clear that BWRs, in general, release more noble gas effluents than PWRs. However, the overall trend shows a drastic decrease in the release rates over the last few decades; approximately 99.9% decrease for BWRs and even more so for PWRs over the considered time period. This is in keeping with the ALARA principle and also indicative of the continuous upgrades made to reactor plants. In the case of noble gas effluents, the primary contributors here are improved fuel pin integrity and use of advanced off-gas treatment systems.

For reductions in radioactive release for day-to-day operations, the design elements that provide greatest impact are improvements in fuel rod fabrication methods aimed at operational integrity, radionuclide filtering systems used in the primary and secondary water loops, and chemistry monitoring and control systems. With the solid fuel enclosed in zircaloy cladding, the

fuel pellets and the cladding themselves are barriers to fission product release. However, there is no such thing as a perfect manufacturing method and microfractures are present in the cladding. Furthermore, noble gases and tritium may diffuse through the cladding. But as Fig. 2 demonstrates, considerable improvements have been made leading to orders of magnitude decrease in noble gas effluent release. The NRC classifies radionuclides other than tritium, ^{14}C , and noble gases that are present in liquid effluents as mixed fission and activation products (MFAP). Fig. 3 shows a similar trend to Fig. 2 in the release of MFAPs from normal operation of PWRs and BWRs. Again, improved fuel integrity plays a part, but effective reductions have been made through the

Fig. 3 Long-term trend in mixed fission and activation product effluents in liquid discharge from US reactors. Source: US NRC.

adoption of liquid effluent treatment systems including ion exchange resins and other filtration equipment (U.S. Nuclear Regulatory Commission, 2019).

It is clear from Fig. 3 that BWRs consistently release less MFAPs than PWRs. Here, the difference comes down to operation practices. BWR operators have adopted a zero liquid-release strategy whereby the reactor cooling water is reused with only tritium released as a gaseous effluent. This means that only the inventory of the MFAPs that is filtered out by cooling water treatment systems is released. Since PWRs use soluble boron in the primary coolant for management of excess reactivity, reuse of cooling water is not practical. Regardless, it is clear that there is a long-term trend showing reductions in the MFAPs released from routine operation of US reactors.

Monitoring of coolant consists of measurements of pH, any additives for corrosion control, and in case of PWRs, soluble boron concentrations. Regular records of measurements of radionuclide concentrations in the coolant provide benchmarks for source term analysis methods. The particulars of the activated corrosion products depend on the choice of materials. Some activation products have limited solubility in water and get deposited on various surfaces throughout the primary loop. Ever so often, these plated out activation products get dislodged and resuspended in the coolant loop leading to temporary spikes in the coolant radioactivity measurements. One example of such an activation product is ^{60}Co .

Radioactive gas treatment systems for BWRs implement delay lines while PWRs use gas holdup tanks that allow for the shortest-lived isotopes to significantly decay away. Longer term holdup times for BWRs are achieved through the use of activated charcoal beds where noble gases adsorb onto the surface of the charcoal. The details of volume, flow rates, holdup times, and overall effectiveness of such gaseous and liquid effluent treatment systems are important considerations when estimating the operational source terms from a given reactor plant. Several computer programs have been devised for making such calculations. The NRC code used for this purpose is called Gaseous and Liquid Effluent (GALE) with PWR and BWR-specific versions (Bangart et al., 1978, Chandrasekaran et al., 1985). The codes provide default inputs based on the ANSI/ANS-18.1-1999 standard for calculations when specifics are not available (American Nuclear Society, 1999). They also allow the user to adjust the parameters to match the specific performance characteristics of the reactor plant being analyzed for a more accurate description of the source release.

Radiation releases from LWR accidents

It is an unfortunate reality of the modern world that failures occur in engineered systems. Nuclear reactors, although shown to be one of the safest sources of energy (Wang, 2011), are not immune to accidents. Even the best designed systems cannot be fully immune to equipment failure. With human beings involved in design and operation, errors can occur which may lead to a scenario where radioisotopes are released to the environment. Some of these factors have a higher frequency of occurring than others. Unforeseen natural disasters can lead to a cascade of malfunctions leading to BDBAs. By their very nature, less frequent BDBAs are more difficult to characterize. In the case of DBAs, the damage extent can be characterized and planned for in advance. Calculations are made to estimate the magnitude of radiation releases and strategies, such as engineered safety features and operator guidance (Lutz and Williamson, 2021a,b,c) are implemented to minimize impact to the public and the environment.

There have been a relatively small number of accidents in the history of nuclear reactors that have led to significant radiation release. It should be noted that even though in total the cost of these accidents has been significant, the times where radiation posed a significant concern for public health are exceedingly rare. Furthermore, as emphasizes in Skillman and Rempe (2021), Sich (2021) and Mizokami and Rempe (2021), past events have increased our understanding of radiation release from an accident.

Estimating source release from an accident is more of a predictive science than a deterministic one. Even though the exact sequence of an accident is difficult to predict, the scope and risk from postulated events can be estimated with some uncertainty. With this in mind, regulatory bodies seek to ensure the safety of the public and to reduce any undue risk. As described in Bley and Malsch (2021a,b), US federal regulations that govern LWR are enumerated in Title 10 of the Code of Federal Regulations (CFR). In addition to the regulations, there are guidance documents for determining the consequences for DBAs as well as BDBAs. When requesting a license for any reactor, the designers must evaluate possible releases for selected PIEs, and then demonstrate that the facility design can adequately mitigate releases such that the regulatory limits are met. All analysis models and input assumptions must be supported with evidence to show that they reasonably capture the underlying physics of the radioactive release and accessible environmental transport pathways. Additional measures, such as backup safety systems, are required for defense-in-depth (Rempe and Williams, 2021). Part 100 of Title 10 CFR deals with reactor siting criteria and specifies requirements for the exclusion zone, low population zone and population center distance for a proposed plant location. Depending on the reactor site, the accessible pathways for environmental transport of radionuclides can be evaluated. Certain pathways are more accessible than others depending on the geology of the reactor site and the surrounding biosphere. Taking into account the available transport pathways, the exclusion zone is set such that any individual located at any point of the boundary would receive a maximum dose of 25 rem to the whole body (or 300 rem to the thyroid from exposure to iodine) 2 h post release.

As mentioned earlier, the fission and activation product inventory in nuclear reactors forms the bulk of the initial source term. The nature of the release source term which accounts for that fraction of the initial source term that volatilizes out of the fuel and is released to the biosphere depends largely on the specifics of the accident that occurs. Depending on the dose being calculated, certain radionuclides are more important than others due to their behavior in the environment as well as their propensity of being taken up by humans (EPA, 2017). ^{131}I is one such important radionuclide that is highly radioactive and is preferentially concentrated in the thyroid gland. ^{131}I can be combated by consuming potassium iodine that saturate the body with stable iodine and

reduce absorption of radioactive iodine. ^{90}Sr is an isotope of interest due its long biological half-life and preferential concentration in bones and teeth. Another important radioisotope for latent dose calculations is ^{137}Cs , which is an analogue to potassium in living cells, and can travel readily through the biosphere. These radioisotopes, in particular, pose significant health risks to the public and are of great interest when evaluating the release source term.

As discussed in [Sich \(2021\)](#), an International Nuclear (and radiological) Event Scale (INES) was developed by the International Atomic Energy Agency to rate the severity of nuclear accidents after the accident at Chernobyl Unit 4. There have been two INES level-7 events (highest level) in history: the event at Chernobyl Unit 4 (ChNPP4) and at Fukushima Daiichi (1F).

The Chernobyl accident was precipitated by human error coupled with a poorly designed reactor and an improper design of an experiment at low power. [Sich \(2021\)](#) provides details. It is widely considered the worst nuclear power plant accident and perhaps the worst possible accident. One of the design faults of the RBMK reactors deployed at Chernobyl is a positive void coefficient of reactivity. As reactor power and coolant temperature increased during a low-power experiment, the water coolant started to boil leading to an increase in reactivity and correspondingly increase in power. Eventually a runaway chain reaction developed leading to the explosion of the core. Nearly all power reactors are required to have a negative reactivity feedback, and a Chernobyl type reactor would not be licensed by any regulatory organization in other countries. The Chernobyl reactors also did not have a containment building which led to an unabated release of radioactivity into the environment. The exact amount is debated, but an estimated source term for the accident is given in [Table 3](#). The accident itself was kept secret until radioactive material had traveled through the atmosphere to other countries ([Sich, 2021](#); [United Nations, 2020](#)).

The disaster at the Fukushima Daiichi (1F) reactor plant, which included six BWRs ([Mizokami and Rempe, 2021](#)), was the result of a BDBA sequence resulting from a strong earthquake and a subsequent tsunami. With existing disruptions caused by the earthquake, the reactor plant was struck by an up to 15-m tsunami wave—well above that predicted by the plant design engineers. As a result, the backup diesel generators were rendered inoperable and the reactor cores of the three operating units at 1F were left without sufficient cooling water leading all three cores to their meltdown. At the greatly increased temperatures, the zircaloy cladding oxidized by reacting with the water/steam to form free hydrogen gas. The now oxidized cladding also released the contained volatile fission products. The over pressurization caused by the steam, hydrogen, and fission gas mixture forced operators to vent the gases which led to the accumulation of explosive concentrations of hydrogen in the upper part of the buildings in two of the operating units (1F1 and 1F3) and one building of a unit that was shutdown for refueling (1F4). Combustion of the accumulated hydrogen led to explosions that also dispersed volatile isotopes of iodine, cesium, and xenon into the atmosphere. [Table 4](#) shows

Table 3 Representative source term for the Chernobyl accident ([Metivier, 2002](#)).

^{137}Cs	12.4 ± 2.5

an estimate atmospheric release source term from the Fukushima Daiichi nuclear power plant. Interestingly, there were several warnings issued by the IAEA and Japan's own regulatory bodies regarding the vulnerability of Japanese reactors to earthquakes and flooding from tsunamis (Bloomberg, 2012; Krolicki, 2011). However, the suggested measures were never implemented.

As described by Skillman and Rempe (2021), the Three Mile Island Unit 2 (TMI-2) accident is the only core melt accident in a commercial PWR in the United States where there was a release of radioactive material to the public. The accident resulted in a partial meltdown and release of relatively small quantities of radioisotopes above regulatory limits. It is widely agreed that there were no adverse health effects as a result of the accident. TMI is historically important because it showed that core melt accidents can occur in commercial PWRs and that the release mode and accident progression are important in estimating the release source term. As emphasized by Soffer et al. (1995), the quantity of radionuclides released were well below those predicted during licensing. Moreover, the initiating event at TMI-2 (a malfunctioning overpressure relief valve) had been previously observed at a different plant with the same reactor design (Drummond Ayres, 1979). The TMI accident led to many lessons learned (Skillman and Rempe, 2021), including the need for better information sharing among reactor operators. It also provided data for reducing uncertainties in source term release estimates.

Many computational tools are available to help reactor designers predict radiation release from a given reactor accident sequence. One such widely-used tool is MELCOR (MELCOR, 2017). It was developed by the NRC to predict accident progression and radiation releases. MELCOR can address a wide variety of accidents and provides reasonably accurate predictions of the radiation released from accident for which there is relevant prior knowledge. The chief drawback is that MELCOR is developed specifically for LWRs. The NRC is engaged in expanding MELCOR models for non-LWRs. However, data for validation of such models is limited. Likewise, developers wishing to license non-LWR reactor designs will have to use a different analysis tool which have not been rigorously benchmarked due to limited validation data. Perhaps, current codes could be expanded to become applicable to other types of reactor designs. Most upcoming advanced reactors (Stanculescu, 2021) are envisioned to be immune to some types of accidents encountered in LWRs. However, accidental radiation release is still possible, and the full scope of such accidents is not yet understood. There is a significant amount of research that is on-going to fully understand accidents in advanced reactors to limit their uncertainty. However, most, if not all, of the advanced reactor designs are expected to be safer than LWRs, but that is not to say that LWRs are not already very safe with a proven track record.

Used nuclear fuel

The fuel extracted from LWRs (and any other type of nuclear reactor) contains many of the fission products, and it generates a significant amount of decay heat. As a result, the fuel needs to be first stored in a way to dissipate heat. After this initial storage, the fuel can either be reprocessed and recycled or sent for long term storage. Each option has its own associated source term. In this section, the source terms from the storage of LWR spent nuclear fuel is explored.

Spent fuel from a reactor is intensely radioactive owing to the decay of fission and activation products and the accumulation of trans-uranium isotopes (actinides). These radioactive nuclei decay over time and eventually become stable. Fig. 4 depicts the normalized activity of spent nuclear fuel over time and highlights the important component isotopes that contribute to the radiotoxicity. In order to compare used nuclear fuel's activity or radiotoxicity with that of the uranium ore it comes from, the grade of ore and radioisotopes must be known. Therefore, these comparisons are not included in the article. Storing the spent fuel would ideally isolate these harmful radioisotopes from the environment. Regulatory requirements exist that limit the release amounts (NRC Title 10 CFR Part 72). To accomplish this isolation, several storage options have been developed. This section will look at the three largest: spent nuclear fuel pools, dry-cask storage, and geological repositories.

Spent fuel forms and waste streams for advanced reactors can diverge significantly, and the corresponding source terms will not be explored in this article.

Immediately following the removal of spent fuel, the shortest lived isotopes produce the most significant amount of heat. To properly disperse this heat, the spent fuel is stored on-site in pools of demineralized water. These spent nuclear fuel pools dissipate heat and provide radiation shielding to on-site workers. The water also consists of soluble boron to prevent nuclear criticality. When considering source terms from the spent fuel pools, the release rate is low but still present. There are multiple barriers against the release of radioactive material in a spent fuel pool. Most of the possible source material remains in the fuel inside the cladding. For high burnup (what would be typically seen in waste storage), the failure rate for cladding is about 1% (Ahn et al., 2012). From there, the majority of fission products that do escape remain in the water, but some like the gaseous fission products do escape over time. The failure rate can increase if the fuel assemblies are dropped during transportation (Kamas et al., 2006). Additionally, the cladding failure outside the pool can lead to oxidation (UO_2 to U_3O_8), which in turn, increases fission product escape from the stored fuel rods.

Following a cooling down period of 10 or more years, the spent fuel can be moved to dry cask storage, which are an increasingly used option for long-term spent fuel storage, the dry casks are stored on-site although they could be consolidated at a dedicated storage facility. In the dry cask made of steel and concrete, the spent fuel assemblies are put into a canister filled with inert gas before being placed into the cask. The steel and concrete surrounding the spent fuel provide radiation shielding. There has been no significant leak of radioisotopes observed from the spent fuel while in dry cask storage, and a leak does not seem likely in the foreseeable future. In the NRC report on the Holtec independent spent fuel storage facility, the conclusion was that the only significant source would be from gamma radiation that penetrate shielding (U.S. Nuclear Regulatory Commission, 2020).

Fig. 4 The activity of radionuclides in spent nuclear fuel for a PWR with 4.5% enrichment and 50 MWd/kg. Source: digitized from Xu Z, Kazimi MS, and Driscoll MJ (2005) Impact of high burnup on PWR spent fuel characteristics. *Nuclear Science and Engineering* 151(3): 261–273.

Dry cask storage on the surface could be indefinite, but the current plans call for about 40 years of cask storage followed by longer-term geologic disposal. Such geologic disposal sites are designed with the purpose of creating extreme separation between the biosphere and the nuclear waste. The only major pathway that radioisotopes could take to travel back into the environment is through groundwater. A study of the KBS-3 canisters used at the Onkalo geological storage site in Finland found that there would be no significant radiological damage or corrosion of the canisters (Yang et al., 2019). Any breakage of the canisters would have to result from the slow movements of the Earth's crust. Such geological scale events are far longer than recorded human history, and if a site is chosen correctly, there would be little tectonic activity or groundwater penetration.

All told, each of these storage options has little chance of exposing the public to a significant dose of radiation. This is because the spent fuel has a predictable activity and the storage sites are fairly stable. The greatest risk of source release is from the transportation of the spent fuel since drops could lead to breakage and oxidation. However, there has been no significant release that has occurred during transportation of spent nuclear fuel (IAEA, 2018).

Introduction

The field of external dosimetry is focused on the determination of delivered doses to persons from radiation sources outside the body. This may include individual radioactive sources, man-made radiation (i.e., X-rays), radioactive contamination, cosmic rays, and other nuclear radiation sources. In general, the radiation is detected (measured) using detectors worn on or near the body and some interpretation is then made to convert the signal received by the detector to the dose received by various parts of the body. The system of external dosimetry is, in some ways, unchanged from when it was first conceived over a hundred years ago when nuclear radiation was first discovered. Technology has certainly advanced, but many of the assumptions, interpretations, and limitations remain. This article will introduce regulations and standards applicable to external dosimetry programs, discuss the philosophy of external dosimetry, review common available technologies, provide a review of dose coefficients used in the assessment of external dose, and develop a simple example of how a dosimeter may be used to determine doses delivered from a mixed radiation field and sources via a dosimeter algorithm.

Regulations, standards, and accrediting bodies

There are two primary regulatory drivers for personnel dosimetry in the United States—10 CFR Part 20 (US DOE, 1991) and 10 CFR Part 835 (US DOE, 2007). Part 20 applies to facilities regulated by the Nuclear Regulatory Commission, which includes commercial nuclear power sites, hospitals, universities, and commercial interests. Part 835 applies to Department of Energy sites. Each of these regulations places occupational dose limits on personnel—5 rem/year for the whole body, 15 rem/year to the lens of the eye, and 50 rem per year to the skin that includes the extremities (wrist, ankle, and finger). For both 10 CFR 20 and 10 CFR 835 the occupational dose limits are given in terms of the protection quantities; although, the quantities themselves are different between the two regulations. 10 CFR 20 follows the protocols of the International Commission of Radiological Protection (ICRP) Publication 26 including the use of effective dose equivalent while Part 835 was revised in 2007 to use ICRP Publication 60. So, there are inherent (and important) differences between the two. The differences between ICRP 26 and ICRP 60 are many, including the application of different methods for converting energy absorbed in tissue (dose) to a dose that takes into account different type of radiation and different types of tissue. These methods have changed over the past 120 years and so has terminology. Methods used in regulatory documents are not the same as those that are currently considered best practices among radiation protection professionals. For example, neutron quality factors recommended in ICRP 26 differ from those of ICRP 60. While both ICRP 26 and ICRP 60 use risk-based approaches for the protection quantities, there are differences in organ and tissue weighting factors, radiation weighting factors, and terminologies. As a result, individuals exposed to similar radiation fields under ICRP 26 and ICRP 60 protocols may be assigned slightly different doses; however, this is of no concern from a radiation risk perspective.

Applicable standards

ANSI N13.11

The American National Standards Institute (ANSI) published a standard, ANSI N13.11 (ANSI, 2009) that describes a procedure for testing the performance of whole-body dosimetry systems for monitoring personnel exposure to ionizing radiation. Performance testing is conducted under controlled conditions, and it includes irradiation with photons, beta particles, neutrons, and mixtures of these radiations. This standard provides the basis for whole-body dosimeter testing under the two primary dosimetry accreditation programs in the US, namely the Department of Energy Laboratory Accreditation Program (DOELAP) and National Voluntary Laboratory Accreditation Program (NVLAP) to be discussed in following sections. Under ANSI N13.11 a program may test under various categories, with each category representing radiation fields applicable to the site or program. Accident level doses are available for photon testing. For routine dose levels, the available categories include photons and photons mixtures (with energies ranging from 20 keV to 1.33 MeV), low and high-energy beta fields, photon and beta source mixtures. Photon fields include discrete energies as well as a variety of X-ray spectra. Neutron sources used for testing are unmoderated and D₂O-moderated ²⁵²Cf, and neutron and photon mixtures. ANSI N13.11 provides specific limits for mixtures categories. Testing results are evaluated using criteria described in the standard.

ANSI N13.32

While ANSI N13.11 applies to whole body dosimetry, a separate testing standard, ANSI N13.32 (ANSI, 2008), applies to extremity monitoring. The standard applies to dosimetry systems used to assess personal dose equivalent at a depth of 0.07 mm in International Commission on Radiation Units and Measurements (ICRU) tissue in extremities, specifically, to the performance of dosimeters worn on fingers and on wrists or ankles.

ANSI N13.32 testing categories include high and low-energy photons, high and low-energy beta particles (including ⁹⁰Sr, ⁸⁵Kr, and depleted uranium), and limited mixtures of these. At the present it does not include testing categories for neutrons.

Both N13.11 and N13.32 are strictly dosimeter performance test programs and do not contain guidance for the administration of dosimetry programs such as reporting, field calibrations and corrections, dosimeter placement on workers, or the use of multiple dosimetry. Requirements for some of these program aspects are provided in the accreditation programs DOELAP and NVLAP.

External dosimetry accreditation programs

There are two primary accreditation programs in the United States for dosimetry programs—the US Department of Energy Laboratory Accreditation Program (DOELAP) and the National Voluntary Laboratory Accreditation Program (NVLAP). These programs are briefly described in the following sections. Both accreditation programs follow the dosimeter performance testing protocols described in ANSI Standards N13.11 and N13.32.

National Voluntary Laboratory Accreditation Program (NVLAP)

The National Institute of Standards and Technology (NIST) Handbook 150-4 (Ho, 2019), NVLAP Ionizing Radiation Dosimetry, presents the technical requirements and guidance for the accreditation of laboratories under the NVLAP Ionizing Radiation Dosimetry Laboratory Accreditation Program. The laboratory accreditation program for Ionizing Radiation Dosimetry was established in 1984 in response to a request from the U.S. Nuclear Regulatory Commission (NRC). The purpose of the NVLAP Ionizing

Radiation Dosimetry Program is to recognize competent dosimetry processing laboratories and to improve the quality of personnel dosimetry by providing periodic evaluations of each laboratory, including an assessment of the laboratory's management system (Ho, 2019).

Accreditation is available to any laboratory that processes radiation dosimeters used to monitor individual exposure to ionizing radiation. A foreign-based laboratory may also be accredited by NVLAP if the laboratory meets the same requirements as domestic laboratories and pays any required additional fees associated with the on-site assessment (Ho, 2019).

Department of Energy Laboratory Accreditation Program (DOELAP)

The Department of Energy (DOE) implemented the DOE Laboratory Accreditation Program (DOELAP) for external dosimetry in 1986. The objectives of the DOELAP external dosimetry program is to assure the competency of dosimetry measurements through calibration inter-comparisons, performance testing, on-site assessments; and to encourage applied research in areas where there is a technology shortfall. DOE also expects the program to enhance cooperation and technical information exchange among its sites and facilities to provide a more standardized and uniform radiation dosimetry capability. DOE sites and facilities are expected to use standards and other technical guidance from the Department to ensure that the performance of personnel dosimetry programs are adequate to meet the requirements of 10CFR835 (US DOE, 2018).

DOELAP accreditation involves performance testing of dosimeters and the documentation of program elements important to the long-term quality assurance of a dosimetry program and its ability to accurately measure, record, and report occupational whole body and extremity dose (US DOE, 2018). On site assessments are conducted triennially by dosimetry program experts who are selected from participating organizations. These assessors undergo recurring qualification training conducted by the DOELAP administrators.

Quantities, calibrations, and phantoms

The foundation of a dosimetry program is its ability to accurately and reliably determine the dose delivered to a person. Since the dose is not measured in the person, a dosimeter is used as a surrogate and this dosimeter must be referenced against, and traceable to, a national standard. The standard of radiation dose is provided by a calibration facility that performs the dosimeter irradiations using methods described in the relevant ANSI standards. For testing purposes the methods of irradiating dosimeters, the sources and phantoms to be used are described in the relevant ANSI standards. Calibration facilities follow strict protocols to ensure the quality of exposures are acceptable. The two primary categories applicable to external dosimetry are whole body and extremity. The radiation protocols for each are briefly described below.

Whole body

For purposes of dosimeter calibrations to obtain operational quantities, the dosimeters must be placed on a phantom that provides a reasonable approximation to the backscatter properties of the part of the body on which the dosimeter is worn. The phantom used for whole body testing is a polymethyl-methacrylate (PMMA) rectangular slab with dimensions $30 \times 30 \times 15$ cm thick for photons and neutrons. Backscatter measurements (when a source particle scatters from material external to a detector back into a detector) are used to verify adequacy for photon irradiations. A $40 \times 40 \times 15$ cm phantom is sometimes used for neutron dosimeter testing. For beta irradiations the same area is used, and the thickness must be at least 5 cm. Specifications are provided in the standard for dosimeter mounting and for minimum irradiation distances. For photon and neutron testing, dosimeters are not mounted near the phantom edges to eliminate radiation scattering effects for these positions.

Whole body irradiations are performed in order to test a dosimetry system's ability to calculate reference doses. For each of these measurements, methods for converting the measured air kerma ($\text{Kinetic Energy Release per unit MAss}$) to the operational quantities of interest are provided in the ANSI standard. Thus, the irradiation facility measures the air kerma and from this measurement applies the conversion to arrive at the reference dose for the quantity of interest such as personal dose equivalent.

Extremity

There are two phantoms used in the extremity dose testing—the rod to simulate the ankle or wrist and the pillar to simulate the finger. The rod phantom is a solid, right circular PMMA cylinder with a diameter of 19 mm while the arm phantom is a solid, right-circular PMMA cylinder with a diameter of 73 mm. Both the rod and pillar phantoms are 300 mm in length. Testing categories include: high-dose photons, photons with energies between 20 keV and 1.33 MeV, high and low-energy betas, depleted-uranium slab, and mixed fields, where testing may be blind or non-blind. Many extremity dosimeters contain a single element so only a single correction factor is required to convert the signal on the dosimeter to dose. Since only a single factor is used, the reference field must be known (to the test participant) so the appropriate correction factor may be applied.

For both the whole body and extremity testing programs, it is the responsibility of the individual site to determine the categories to be tested. These should be based on the radiation fields encountered at the site.

Dose coefficients

Overview

Dose coefficients (sometimes referred to as dose conversion coefficients) relate the incident fluence (total path length of all particles that have passed through a unit volume) of particles to a corresponding dose quantity in tissue. The coefficients that convert fluence to dose vary as a function of incident particle energy, and they are computed using representative phantoms. The complexity of some of these phantoms has evolved as computing capabilities has increased. Consequently, the ability to more accurately calculate delivered doses to reference phantoms has dramatically improved. Early phantom models were commonly defined in simple geometric shapes such as spheres or cylinders. For operational quantities, these simple phantoms are still used. During the past several decades, phantoms designed to obtain protection quantities for individual organs and tissues have become more realistic with increasingly sophisticated mathematically described phantoms. More recently volumized-pixel (voxel) phantoms have been created based on high-resolution medical images of humans. The latest recommendations from the ICRP utilizes these phantoms for determining radiation protection quantities (ICRP, 2007, 2009, 2010). A full discussion on the development, calculation, and variabilities of these coefficients is too lengthy to be included here. A brief review of their history, calculation, and use is provided for the convenience of the reader.

Protection or operational quantities (doses of various types) are calculated based on physical specifications that describe the radiation field and on dose coefficients applicable to a particular radiation field and to a specified physical environment. For practical applications, conversion coefficients applicable to a field quantity (fluence or air kerma) are converted to the operational quantity based on methods appropriate for the reference phantoms (ICRP, 1996, 2007, 2009, 2010; ICRU, 1998).

Sets of dose coefficients were published by ICRU in Reports 43 (ICRU, 1988) and 47 (ICRU, 1992), and jointly with the ICRP in ICRU Report 57 (ICRU, 1998) and ICRP Publication 74 (ICRP, 1996). In Publication 103 (ICRP, 2007), the ICRP reviewed the protection quantities, including effective dose, originally introduced in ICRP Publication 60 (ICRP, 1991). Dose coefficients that transfer physical quantities to the revised protection quantities were published in ICRP Publication 116 (ICRP, 2010). These dose coefficients were computed for a wide range of particles (including those occurring only in cosmic radiation and at particle accelerators) and for an energy range reaching, in some cases, up to 200 GeV. The report identified energy ranges for photons and neutrons where the operational quantities introduced in ICRU Reports 39 (ICRU, 1985) and 51 (ICRU, 1993) deviated significantly from the protection quantities.

Operational quantities rely on phantoms for their definition and for the calculation of dose coefficients (i.e., converting field quantities to the personal dose equivalent). The phantoms and the methods of calculation introduce inconsistencies to the system of dosimetric quantities for radiation protection. Most recently, the ICRP and ICRU have modified the operational quantities to more realistically approximate the corresponding protection quantity. It was noted that the evaluation of personal dose equivalent at a single, defined depth does not reflect the geometric complexity of the human body with numerous organs implicitly present in the definition of the protection quantities. There are some discrepancies when using quality factors for operational quantities and radiation weighting factors for protection quantities. Also, the personal dose equivalent is defined at a depth, d , at a specific location in the body, but for the calculation of dose coefficients simple geometrical bodies like slabs, cylinders and rods are used. The lens of the eye and the local skin have been monitored with a dose equivalent quantity for deterministic effects, which depend, to our best knowledge, on absorbed dose. The most recent guidance is that absorbed dose without radiation quality modifiers should be used for these quantities. Historically dose coefficients for operational quantities have been calculated and published using the kerma approximation. This assumption does not consider the consequences of charged particles created in various reactions from uncharged radiations and can lead to overestimates of dose. Instead, kerma calculations were employed whereby all energy from reactions were assumed to be deposited at the location where the interaction occurred. This assumption neglects the importance of charged particle equilibrium (CPE). For photons in tissue, CPE is lost at about 3 MeV at a 1 cm depth, at about 700 keV for a 0.3 cm depth, and around 65 keV at a depth of 0.007 cm (Veinot and Hertel, 2011). For neutrons, similar discrepancies exist, predominantly at intermediate and high energies (Veinot et al., 2020).

Dosimeters

Thermoluminescent dosimeters

Thermoluminescent dosimeters (TLDs) are among the most widely used for personnel dosimetry and the most common thermoluminescent (TL) materials include LiF, CaF₂, Li₂B₄O₇, and CaSO₄. Each of these materials is mixed with small impurities called dopants. The dopant materials provide lattice sites in the crystalline structure that can be occupied by electrons. As will be discussed later, an advantage of LiF over the other materials is its near tissue equivalent absorption and scattering properties, resulting in a close response to the dose equivalent response in tissue for photons.

Trap formation

The scintillation (light emission) process depends on energy states that are determined based on a material's crystalline lattice structure. In insulators and semi-conductors only discrete energy states are available for electrons. Bound electrons are maintained at the lower energy band (called the valence band) while higher energy state electrons are found in the conduction band. Conduction band electrons can migrate through the material creating current. The region between the conduction and valence bands is called

the forbidden band and, in pure crystals, electrons are not allowed to exist in this region. The forbidden band separates the conduction and valence band by a distance (energy) called the band gap. If an electron in the valence band absorbs energy equal to or greater than the band gap energy, it can be elevated to the conduction band. Once this energy is expended it returns to the valence band and emits a photon in the process (Attix, 2008). Typically, this band gap energy is beyond the visible light range where the wavelength of light can be found from the photon energy (Eisberg and Resnick, 1985):

$$E_{\gamma} = h\nu \quad (1)$$

where E_{γ} is the photon energy, ν is the frequency, and h is Planck's constant.

Additional energy states are allowed when impurities (called dopants) are added to the material. Valence band electrons can be elevated to one of these activator energy states creating electron-hole pairs of energy less than the band gap energy. These electron-hole pairs may have recombination energies that are in the visible light range. The de-excitation of these trapped electrons has a low probability at room temperatures because the distance between the trapping centers and the conduction band is too large, and the energy created by incident radiation remains trapped. As more energy is deposited additional traps are formed within the TLD. The characteristics of the TLD are determined by the materials and dopants (activators) used to construct the dosimeter. A schematic showing the energy levels, conduction and valence bands, and band gap is shown in Fig. 1.

Glow curve emission

The probability that an electron will escape an activator trap site is governed by the Boltzmann equation:

$$P = Se^{\left(\frac{-E}{kT}\right)} \quad (2)$$

where S is a normalization constant, E is the trap depth (or the energy of the trap below the bottom of conduction band), T is the temperature, and k is the Boltzmann constant ($8.617 \times 10^{-5} \text{ eV K}^{-1}$) (Eisberg and Resnick, 1985; Knoll, 1989). As the temperature increases additional energy is available to the trapped electron and the probability of escape from the trap increases. Adding additional energy to the system via heating accelerates the process as deeper traps are emptied as the temperature increases. Most TLD materials have multiple activator energy states and simply heating to a single temperature may not empty all available traps. As the TLD is heated to higher temperatures, additional higher energy traps will empty and a characteristic glow curve for the material is produced. As the temperature is maintained the total probability of trap depletion increases (Knoll, 1989). For LiF TLDs doped with magnesium and titanium the energy band gap is approximately 10 eV (Horowitz, 1984) with the activator energy states having de-excitation energies between approximately 140 °C and 300 °C.

Most TLD readers will heat the material at a constant rate to some maximum temperature and maintain this temperature for a few seconds. For an equal absorbed dose in the TLD, the intensity of the glow curve (light output as a function of time) is dependent on the material characteristics for a given heating cycle. The energy released during a particular heating cycle depends on the availability and energy depth of available traps as well as the release rates of those traps. Integration of the glow curve over the heating time produces the total signal. Since the heating rate and maximum temperature control the release of trapped electrons it is important that this time-temperature profile be maintained and reproduced to ensure consistent results.

Energy transfer rate dependence

As ionizing radiation enters material, it interacts through various mechanisms with the material creating electron ionization events. These energy transfers may result in free electrons (and their associated positively charged atomic nuclei), kinetic recoil energy of nuclei, or the creation of new nuclei as in the case of the ${}^6\text{Li}(n,\alpha){}^3\text{He}$ reaction. The available traps formed in the band gap are energy dependent and traps are formed at various energy levels beneath the conduction band. Since the traps have varying energy states, deeper traps require more energy transfer to an electron-hole pair. As a result, the number of traps filled that produce electron-hole

Fig. 1 Energy band structure of TL material. The band gap is shown as the energy difference between conduction and valence bands. The activator traps are shown as discrete energy states within the band gap. Scintillation photons are produced during de-excitation to lower energy states.

pairs depend not only on the quantity of incident radiation, but also on the ionization rate and average energy transfer per ionization event of the incoming radiation (Horowitz, 1984). Incident radiation that produces higher ionization energies allows deeper (higher energy) traps in the TLD to be created. Consequently, higher temperatures during heating are required in order to impart sufficient energy to release these traps.

Fade

Based on Eq. (2), it is apparent that filled traps in thermoluminescent material (doped with activators) are not permanent. In fact, over time some traps will release their energy and the electron-hole pairs recombine as a result of instability or thermal stimulation. For some materials, exposure to light can increase the signal loss. Each of these has the effect of reducing the net signal produced during a read and is referred to as fade. The fade properties of a TL material is determined by the TLD makeup including dopants, length of time since anneal, length of time since irradiation, and environmental factors. Since the activator energy traps have varying energy states, the probability of fade is energy dependent. More precisely, traps with lower energy states have a higher probability of recombination due to fade than deeper traps. For practical purposes, it is generally assumed that peaks with short half times (less than a few days) will have decayed to negligible values before the processing of personnel dosimeters is performed. This may not be the case in emergency situations where a dosimeter is retrieved and processed in a matter of hours. This overall impact of signal loss is important and should be quantified by performing fade studies for the particular dosimeter material. The fade is dependent not only on post-irradiation time, but also on the time between anneal and irradiation since the maximum number of available traps are found soon after anneal. Fade studies should consider both determinants. For acute irradiations, the fade can be described as a series of terms having the form:

$$F(t_{pre}, t_{post}) = C_1 e^{\left(\frac{-\ln(2)}{\lambda_1} t_{post}\right)} \left[C_2 + C_3 e^{\left(\frac{-\ln(2)}{\lambda_2} t_{pre}\right)} \right] + C_4 e^{\left(\frac{-\ln(2)}{\lambda_3} t_{post}\right)} \left[C_5 + C_6 e^{\left(\frac{-\ln(2)}{\lambda_4} t_{pre}\right)} \right] + \dots \quad (3)$$

where λ_n is the decay probability of trap n , t_{post} is the time between exposure and read, t_{pre} is the time between anneal and exposure, and C_n are constants determined by the material construction. The number of terms in Eq. (3) will also be determined by the material construction since each term is describing the decay half times of individual traps in the activator band. The fade of different dosimeters should be similar provided they are constructed of the same TL material and dopant (i.e., LiF doped with copper, for example). Different TL materials will have different trap structures and therefore different fade characteristics. In fact, dosimeters of the same TL material composition, but different dopants, may have different fade characteristics.

Background

Background signal accumulation will occur immediately following anneal. This signal on the TLD is a result of background radiation and is commonly assumed to increase at a consistent rate. Environmental factors such as heat, optical stimulation, tribological effects, and other sources can lead to additional signal (traps being filled) in TL material. In general, this effect increases with time after the TLD is annealed. To account for this in practice, an understanding of the accumulation of background signal is necessary.

Since the TLD is an integrating dosimeter, accumulated signal should increase with time. In reality, effects from fade and non-uniform exposures must be considered, and the exposure pattern would be expected to vary, depending on a number of variables. In order to arrive at a reasonable approximation of expected signal over time, background studies are performed. These studies generally involve the placement of dosimeters in various storage areas. They are not stored in process areas nor where they would receive occupational exposures from various sources. After storage the dosimeters are retrieved and read. Often a background accumulation rate is determined under the assumption that the signal is imparted to the dosimeter at a constant rate.

Glow curves

After irradiation thermoluminescent dosimeters are read by heating the TL material. The plot of light intensity as a function of temperature (the glow curve) is integrated to determine the relative dose delivered to the dosimeter material. The light emission produced by heating is detected using a photomultiplier with appropriate optical filters to ensure detection of thermoluminescence while rejecting spurious light from heating of the surroundings or the substrate. Signal processing electronics record glow curves and perform data analysis to produce computations of the dose delivered to the TLD.

Heating of the TLD can be accomplished using a resistance heater, flash bulbs, or gas. Thermocouples are typically used to verify that the correct heating rate is applied to the material since this will affect the emptying of trapping centers. An example of a glow curve produced by a LiF TLD exposed to a $^{90}\text{Sr}/^{90}\text{Y}$ source is shown in Fig. 2. For this example the TLD was pre-heated to 50 °C then the heating was increased at a rate of 25 degrees per second to a maximum of 300 °C. The 300 °C temperature was then maintained for 3.33 s. This glow curve is representative of a TLD that has been exposed to beta and/or photon radiations.

The relationship between trap formation and the type of radiation (such as photons, betas, alphas, and neutrons) impacts the nature of the glow curve. For example, photons transfer energy to material at a lower rate than do alpha particles or neutrons (that produce charged particle reaction products or recoil charged particles). This difference in the rate of energy transfer is often characterized by a term referred to as Linear Energy Transfer (LET). Photos and betas transfer energy at a much lower rate than alphas and neutrons and are referred to as low-LET particles. Alpha particles and neutrons are referred to as high-LET particles. LiF TLDs enriched in ^6Li that have been irradiated with neutrons produce alpha particles and tritons created in the $^6\text{Li}(n, \alpha)^3\text{He}$ reaction, which are

Fig. 2 A representative glow curve of LiF exposed to $^{90}\text{Sr}/^{90}\text{Y}$.

Fig. 3 Glow curve of LiF TLD enriched in ^6Li after irradiation by neutrons.

high-LET particles and lead to more efficient creation of deep traps compared to gamma or beta radiation. Glow curves of these elements indicate traps that are released at high temperatures as illustrated in [Fig. 3](#). For this readout the same temperature profile was used as for the glow curve shown in [Fig. 2](#).

Dosimeters will show some non-linearity of response as a function of dose. At high doses (above 1 Gy for LiF) the response becomes supralinear and must be adjusted to correct for this non-linearity.

Different TL materials exhibit varying responses to photons as a function of energy because of their material composition, trap structure, and interaction mechanism. At low energies LiF has a response that is nearly tissue-equivalent which is advantageous from a dosimetric perspective, while other materials such as CaSO_4 , Al_2O_3 , and CaF_2 over-respond to low energy photons. The differences in the responses of the various materials are due in part on the dependence of photon absorption upon the effective atomic number Z_{eff} and the intrinsic sensitivity of the recombination centers in the crystal structure. The effective Z of LiF is 8.2 while that of tissue is 7.4.

Neutron TLDs

The LiF dosimeters typically issued to personnel for beta/gamma monitoring are enriched in ^7Li , which has a very small response to neutrons. The ^6Li isotope, however, has a strong neutron response with a thermal cross section of 941 b. For personnel that work in neutron fields, the TLD dosimeter contains a ^6Li -enriched chip and a ^7Li -enriched chip. The photon response of the ^6LiF and ^7LiF are similar over a wide energy range (Veinot et al., 1998) so signal on the ^7LiF is subtracted from signal on the ^6LiF to leave neutron signal. The energy response of neutron-sensitive elements can be calculated and has been reported for common dosimeters (Veinot and Hertel, 2001, 2005).

You may notice in Fig. 3 that the tail at high channel numbers (where the 300 °C temperature is being maintained) the deeper traps within the TLD are liberated. The probability of trap release at a given temperature is constant as a function of time and this tail will continue to increase until a statistically significant number of traps have been liberated. At that point the tail will decrease since fewer and fewer traps are available. In this case the glow curve capture stopped at channel 200.

For ^6Li and ^{10}B -based TLDs the response of the TLD decreases as the neutron energy increases (since the interaction cross section has $1/v$ energy dependence) while the dose coefficients tend to increase as a function of neutron energy. This negative correlation between TLD response and dose equivalent must be accounted for when determining personnel neutron exposures from TLD results. To appropriately modify the TLD results for spectral dependence correction factors are applied. The spectral correction factors (SCFs) must be defined for various neutron spectra, although often the specific spectrum is not known. In practice SCFs are determined experimentally by first measuring the dose rate in a neutron field via multisphere detectors and unfolding the field spectra (Bramblett, Ewing, and Bonner, 1960; Sweezy et al., 1998) or through the use of single-sphere "Rem-balls" used for neutron surveys (Veinot, 2008). These dose rate measurements are compared to the measured responses of TLDs by exposing the dosimeters (mounted on a suitable phantom) to the same field.

Extremity dosimeters

Extremity dosimeters are worn when there is an indication that the largest portion of dose equivalent will be received in a particular area such as the fingers or other extremities. Many extremity dosimeters use thermoluminescent detectors that are mounted as part of a plastic ring or wrist band. The dosimetric characteristics of extremity dosimeters are similar to those of the TL detectors described above. For ring dosimeters a single element is often used. For wrist/ankle dosimetry multi-element dosimeters are sometimes used.

Optically stimulated luminescence dosimeters

In some ways optically stimulated luminescence (OSL) dosimeters are similar to TLDs. Both detector types are composed of doped crystalline materials, and both produce visible light with intensity proportional to the delivered dose. One of the most common commercially available materials used as an OSL dosimeter is aluminum oxide. OSL dosimeters must be enclosed in light-tight holders since they are sensitive to visible light. As opposed to TLDs that are heated to produce luminescence, OSL dosimeters are stimulated using light of a specific frequency. The laser light source is of a different frequency than the signal emitted by the OSL. The stimulation light has a wavelength of about 530 nm while the emitted light has a mean wavelength between 370 and 420 nm. Since the wavelength of stimulating light is somewhat near that of the emitted signal, optical filters are used to discriminate the light and only the emission signal is passed to the photomultiplier for amplification and processing. The energy deposited in the OSL by the laser stimulates trapped electrons that can then combine with trapped holes at lattice sites within the crystal known as F-centers (McDonald, 2019), and therefore produces a signal.

The effective atomic number (Z) for Al_2O_3 is about 10.2 so it over-responds (relative to tissue) to lower photon energies where the photoelectric cross section dominates the overall response. Metal filters can reduce this over-response and are often used in dosimeter holders. This over-response is evident as shown in Fig. 4 which compares the response of OSL and LiF TLDs to photons (Mobit et al., 2006).

OSL detectors are insensitive to neutrons, so neutron monitoring requires the use of other dosimeters such as ^6LiF or track etch detectors (to be covered in the next section). The use of radiators (which converts one type of radiation into another) placed on top of the sensitive OSL elements has been attempted to allow the OSL dosimeters to be used for neutron monitoring, but these tests showed little advantage over the use of a separate neutron-sensitive dosimeter (Passmore and Kerr, 2011).

An advantage of OSL dosimeter is the ability to stimulate only a small portion of the sensitive element so only the illuminated portion is processed while the remaining sensitive element retains its signal. This method is often used to "pre-screen" a dosimeter to determine if, for example, a high exposure occurred and a priority read is to be performed. The remaining sensitive element is unaffected and can be read at a later time with little or no signal loss. This ability can be particularly beneficial for dose investigations and dose reconstruction efforts. Of course, this requires the dosimeter be a one-time use since if it was re-issued to a worker an additional signal would be imparted on the dosimeter that would mask the original signal. Thus, a new dosimeter must be issued at each monitoring cycle which may be cost prohibitive if the pre-screening option is used.

Multiple measurements of OSL dosimeters, using pulsed OSL (POSL) stimulation or continuous wave stimulation (CW-OSL) have been reported. Up to 15 independent measurements have been demonstrated for the POSL technique and up to 10 for CW-OSL. At doses of 10 mSv there was a reported loss of signal of less than 3% (McKeever and Moscovitch, 2003).

Other advantageous characteristics of optical stimulation are the relatively high luminescence efficiency, stability, speed of readout, and no requirement for the application of heat to process the dosimeters. The high efficiency of OSL is partly due to the ability to read the dosimeters at room temperatures. Using POSL a very short read time on the order of a few hundred

Fig. 4 Response of Al₂O₃ OSL as a function of photon energy compared to LiF TLD. Data from Mobit PN, Agyingi EO and Sandison GA (2006) Comparison of the energy-response factor of LiF and Al₂O₃ in radiotherapy beams. *Radiation Protection Dosimetry* 119(1–4): 497–499.

milliseconds is typical (McKeever and Moscovitch, 2003). With these short read times, a high throughput can be achieved by OSL processing centers.

Thermal quenching is the loss of luminescence efficiency as the temperature of the material is increased. Since TLDs must be heated to be read, the process of reading the dosimeters leads to a lack of sensitivity. In general, this effect is negligible for modern materials and doses of interest. OSL suffers from thermal quenching since the efficiency of luminescence emission from F-centers decreases as the temperature of the material is raised over the range from approximately 150 °C to 250 °C. Since OSL dosimeters are stimulated using light at room temperature (where luminescence efficiency is a maximum) this effect is minimized (McKeever and Moscovitch, 2003).

Track-Etch (CR-39) dosimeters

Neutron scattering is a primary energy deposition mechanism of fast neutrons. This is particularly true in low- Z materials, especially those with high hydrogen content, such as tissue. On average, the energy deposited by scattered neutrons in hydrogen is one-half the incident neutron energy (Veinot, 2019). Plastics and polycarbonates contain high levels of hydrogen in various chemical forms. One particularly useful from is allyl-diglycol polycarbonate which is marketed as CR-39. When fast neutrons undergo scatter reactions in CR-39 the molecules are damaged along the track of the recoiled particle. When exposed to caustic solvents, such as KOH and NaOH, the CR-39 is etched at a certain rate based on several parameters including the concentration of the etching compound and temperature. The damaged tracks, however, are etched at a faster rate than the undamaged CR-39 leading to the formation of pits in the plastic. These etch rates are referred to as the track etch rate, ν_t , and the bulk etch rate, ν_b . As the CR-39 is exposed to higher neutron fluence the pit formation increases. By counting the number of pits after etching the incident neutron fluence can be inferred. The etching process can be enhanced through the application of an electric field during etching.

Neutrons do not cause direct ionizations by themselves but by secondary particles resulting from scattering between them and target nuclei. Most tracks are produced by recoils of particles from scattering reactions with hydrogen, carbon and oxygen nuclei. Tracks can also be induced by charged particles created via (n, α) reactions (Milenkovic et al., 2011). Proton recoils are the most predominant and their energy strongly depends on the angle of collision following the laws of mechanics. The recoil protons are emitted in different directions and their latent tracks are oriented randomly in all directions. Some tracks will be etched from the point where the particle was created, while others will be etched from the point where the particle was stopped or from where it left the CR-39 detector. The first case is called direct etching, because etching was in the direction of particle motion and the second is called reverse or opposite etching (Milenkovic et al., 2014).

Not every recoil proton will be able to produce a readable track. The creation of visible tracks (those tracks that will be able to read after processing) is dependent on the incidence angle of the neutron relative to the detector surface. The track etch rate (ν_t) relative to the detector surface normal must exceed the overall bulk etch rate (ν_b) for a readable track to be produced. The critical angle, θ_c , is dependent, among other variables, on the etching process, chemical concentrations, electric field strength (for electrochemical etching), and the equipment used to read the tracks. The critical angle is generally defined as

$$\theta_c = \arcsin \frac{1}{\nu} \quad (4)$$

where $\nu = \nu_t / \nu_b$

Fig. 5 Energy dependence of CR-39. The CR-39 response is bolded while the other curve includes a thermal neutron radiator. A scaling factor of 50 has been applied to the CR-39 with radiator detector response for plotting (IAEA, 2001).

The neutron energy response of CR-39 is negligible below a few 100 keV, depending on the etching mechanism, but it remains relatively flat above this value. To allow the detection of low-energy neutrons a radiator can be placed over the CR-39. This radiator is often a material that emits energetic alpha particles following absorption reactions with thermal neutrons. A representative energy response curve for CR-39 is shown in Fig. 5 along with the response for CR-39 that utilizes a radiator to enhance the low-energy neutron response. The energy dependence of the neutron cross section for the radiator is evident.

At relatively high doses the density of tracks makes the counting of individual pits impossible. At these doses the dose is instead determined by examination of light transmission which is reduced due to the high density of tracks.

System calibration

Modern personnel dosimeters often contain multiple sensitive elements. These elements are placed behind various filters in order to better determine the type of radiation incident on a dosimeter and of its energy. For mixed radiation fields (i.e., beta/gamma and/or neutron) the determination of the type of radiation is a critical step in the assessment of personnel dose. For a personnel dosimetry program there are a number of system calibrations that must be performed in order to correlate the signal present on an individual sensitive element of a dosimeter to the incident radiation type and energy. Finally, once the type and energy of radiation are resolved one must be able to determine the corresponding dose of interest (i.e., dose to the skin, lens of the eye, and/or dose to the whole body).

A dosimetry calibration program typically consists of the following elements: field (personnel) dosimeters, reference (calibration) dosimeters, quality control dosimeters, a dosimetry processing system (i.e., a reader), and standard dosimeter holders. Since there are variabilities associated with each of these, a method for normalizing each of these must be established. This normalization is the system calibration and, in fact, is comprised of multiple individual factors. Ancillary programs such as quality control, blind audit, and maintenance are important for program performance, but not directly relevant to this discussion.

Algorithm calibration

The dosimetry algorithm interprets dosimeter readings and attempts to calculate the dose received by personnel. Multi-element dosimeters are commonly used with each of the individual elements placed behind various filters located on the dosimeter holder. These filters serve to reduce the particle fluence incident on the sensitive elements. Some filters may, for example, discriminate

low-energy from high-energy photons or beta particles from photons. The algorithm is tuned to optimize performance in a variety of radiation fields that may be encountered at the site of use. This optimization is initially performed using a set of reference dosimeters. The reference dosimeter responses to the various fields is used to develop and assess the accuracy of the dosimetry algorithm. Before an algorithm can be used to monitor workers, personnel dosimeters must first be normalized to the reference dosimeter response. This normalization involves multiple steps which will be briefly discussed in the following sections. While the following discussion is specific to TLD and OSL dosimeters, the principles can be applied to other dosimetry systems such as CR-39.

Element calibration

Each of the dosimeter sensitive elements are manufactured using precise quality control measures. Regardless, some fluctuation in overall sensitivities among a sample population is expected. As part of initial and periodic inspection, each element's response is compared to that of a reference population such as a set of dedicated calibration dosimeters. The elemental response correction factors (element correction coefficients, ECC) are used to create a single population of cards with equivalent responses. These factors are applied following dosimeter processing but before input into the dosimeter algorithm.

Reader calibration

The dosimeter reader processes the elements resulting in light emission which is assumed to be proportional to the absorbed dose delivered to the dosimeter. Readers are equipped with photomultiplier tubes (PMT) that amplify the charge created when the emitted light interacts with photocathodes on each PMT. The signal is amplified and collected on charge collection plates. The total signal (Coulombs) from each element is then compared and scaled to reference responses. An NIST (National Institute of Standards and Technology) traceable source may be used to irradiate the calibration cards used for this reader sensitivity calibration. The resulting reader calibration factors are applied to processed dosimeters to calibrate to a reference response.

Local source calibration

Dosimeters used for reader calibration may not be irradiated while enclosed in holders. Instead, only the element responses to the local source are obtained. The dosimeter algorithm is typically calibrated to a reference radiation field such as ^{137}Cs . If a different local source is used, a correction must be applied to account for the differences in elemental responses relative to a NIST calibrated source. Since workers wear dosimeters enclosed in holders a relationship must be established between the response of the dosimeters exposed to the local source and the response of the dosimeter enclosed in the holder mounted on a suitable phantom. This is performed by comparing dosimeters irradiated using the local source with those irradiated by a suitable (i.e., NIST-traceable) source in holders on an appropriate reference phantom. This approach allows the algorithm to maintain traceability to a NIST reference source.

Algorithms

The dosimetry calibration process converts the signal on the sensitive elements (after correcting for competing effects and contributions to signal such as background, fade, etc.), to a corresponding dose quantity. The calculation of dose equivalent (based on readings obtained from individual elements within a multi-element dosimeter) is a complex process and requires evaluating the energy and type of radiation that gives rise to the signals. In addition, the detector elements must have a large enough sensitivity range to enable accurate determination of personal dose equivalent over a wide range of energies and intensities.

The simplest algorithm is one that performs a single correction to the amount of signal on a dosimeter to the delivered dose. Examples include a single-TLD extremity dosimeter worn on the finger or a CR-39 dosimeter worn on the body. In each case a conversion factor must be applied that converts dosimeter response to dose received by the wearer. Since there is only one element it is not possible to determine specifics on the radiation field such as radiation type or energy. For these single-element dosimeters the radiation field characteristics must be known a priori or assumed based on process knowledge.

For multi-element dosimeters as discussed earlier the algorithm attempts to resolve the type and energy of incident radiations. This process is generally accomplished in one of two ways. The two commonly used methods are discussed in the following sections.

Neural network

This type of algorithm is often referred to as a matching or "neural network" type that can also be described as a least-squares-type fitting routine that compares existing results from actual irradiation of dosimeters to those predicted by the algorithm for an unknown radiation field. The basic component of a neural network is a node, and the network typically consists of an input layer of nodes, an output layer, and additional hidden layers in between. The network is connected by links between the various nodes and these links carry specific weights. The functionality of the network lies in ability to modify the various weighting factors. These weighting factors are determined by allowing the network to vary input/output data pairs. The weights are continuously updated by a "learning" algorithm until the network is able to successfully associate the appropriate input with an appropriate output.

The inputs for a neural network dosimetry algorithm are the various signals on the individual dosimeter elements and the outputs are typically the dose equivalent quantities of interest. The sets of input and output data sets are generated using actual dosimeter data for a variety of single and mixed radiation fields. These fields may, for example, include the beta and photon fields

that are encountered at a facility. The mixtures would include beta + gamma fields, mixtures of photon fields, and possibly mixtures of beta fields. Including more types or exposures to the training set the network generally improves the algorithm performance.

The weighting coefficients are calculated by minimizing the difference between the desired output and the actual output of the network. This equation is linear, i.e., it can be expressed as a linear combination of the logarithmic functions and their powers. This linearity makes it possible to use a variety of multiple regression techniques (Perry et al., 1999).

Step-wise or branching algorithm

In a step-wise algorithm various element ratios are compared to one another and decisions are made based on these element ratios. For example, if two elements are compared (where one of the elements is placed behind a metal filter) the combination of these elements may be used to discriminate low-energy photons. If the ratio of the elements meets certain criteria the algorithm may determine that the field contains low-energy photons. The algorithm would then branch to a low-energy photon step. Each step is a process of acceptance or elimination based on Boolean operators. If the required parameters are met, the algorithm has identified the radiation field composition and moves to the dose determination phase. If the parameters are not met a new set of Boolean operators are selected and the process continues until the field is adequately characterized. This process is termed branching in reference to the various branches (or steps) of the algorithm. Each algorithm branch can have sub-categories to further refine the radiation field. Once a step decision is made the algorithm further analyzes the element ratios to determine an appropriate conversion factor to relate element readings to absorbed dose.

Neutron dosimeter algorithms

For neutron monitoring with TLDs, the dosimeter is enriched in a material with strong neutron sensitivity such as ^6Li and neutrons interact with these elements via the $^6\text{Li}(n, \alpha)^3\text{H}$ reaction. Since the absorption cross section of ^6Li is energy-dependent, the response of the TLD will vary with the spectral distribution of the neutron field to which it is exposed. This energy dependence will differ from that of the dosimetry quantity of interest, such as personal dose equivalent. The photon contribution to the ^6LiF element can be eliminated by subtracting the signal on the ^7LiF chip since the photon response of both is similar (Veinot et al., 1998).

The response of neutron TLDs (mounted on a phantom) include contributions from incident and albedo neutrons. These responses as a function of incident neutron energy can be calculated and have been reported (Veinot and Hertel, 2001, 2005) in the literature. For personnel neutron dosimetry a single correction may be applied to account for the spectral energy dependence.

In the case of CR-39 dosimetry a conversion between track density and delivered dose is used. If the CR-39 includes filters or radiators then additional conversion factors are applied. Some CR-39 dosimeters include radiators that enhance the low-energy response and a different conversion factor would be necessary for this element.

Introduction

The field of internal dosimetry focuses on the techniques used to quantify the amount of radioactive material deposited in the human body. It does so by determining the conditions of exposure and by utilizing biokinetic models to evaluate individual biological monitoring data, ultimately resulting in a dose estimate. Various scientific disciplines are involved including physics, chemistry, mathematics, anatomy, physiology, and radiobiology. Estimation of internal dose is a complex process because the magnitude of intake is usually unknown and there is a high degree of biological variability governing the retention and transport processes within the body. There are also differences between radiation sources external to the body and those that are internal to the body. Time, distance, and shielding play key roles in affecting the dose incurred by radiation sources external to the body. By minimizing the time spent around an external source and maximizing the distance and shielding, the external dose can be reduced. However, with radiation sources that are internal to the body, the distance and shielding are fixed by the body and the dose is delivered over time as the radionuclides reside within the body. One way to mitigate potential internal exposures is to implement engineering and administrative controls, such as performing work in a glovebox or utilizing respiratory protection when working with the potential for airborne contamination. Since you cannot see or smell radioactive material that might be taken into the body, there is no immediate way to determine if an internal exposure has occurred without performing some type of monitoring. Therefore, internal dosimetry programs are necessary and important to confirm the adequacy of engineering and administrative controls and to demonstrate compliance with the occupational dose limits set forth in regulatory guidance used to ensure personnel safety.

Basic concepts of internal dosimetry

This section discusses and defines some of the fundamental concepts of internal dosimetry including specific absorbed fractions, source organs, target organs, specific effective energy, equivalent dose rate, and effective dose. To start with, we will define absorbed fraction as that fraction of energy absorbed by the target that was emitted from the source. To gain a visual representation of this concept, consider a source organ, S , from which a radiation of type i is emitted. If target organ, T , of mass M_T , absorbs a fraction of the energy emitted in nuclear decays of the radionuclide present in S , the specific absorbed fraction, $SAF_i(T \leftarrow S)$, is defined as follows:

$$SAF_i(T \leftarrow S) = \frac{1}{M_T} \frac{\text{Energy absorbed by target, } T}{\text{Energy emitted within source, } S} \quad (1)$$

Consequently, the generic equation for calculating the absorbed dose rate in the target organ, T , at time t post intake due to the activity, $A_S(t)$, in the source organ, S , is defined as:

$$D(T \leftarrow S) = A_S(t) \sum_i n_i E_i SAF_i(T \leftarrow S) \quad (2)$$

where $n_i E_i$ = mean energy emitted by radiation, i ; $A_S(t)$ = activity in the source organ; $SAF_i(T \leftarrow S)$ = specific absorbed fraction of radiation, i .

By grouping the factors related to emitted radiations and their contribution to absorbed energy, the coefficient $S(T \leftarrow S)$ can be defined as:

*Retired.

$$S(T \leftarrow S) = \sum_i n_i E_i \text{SAF}_i(T \leftarrow S) \quad (3)$$

By applying the appropriate quality factor for each type of radiation to the $S(T \leftarrow S)$ coefficient one addresses equivalent energy and the resultant coefficient is denoted as $S_W(T \leftarrow S)$. This coefficient previously was referred to as specific effective energy. $S_W(T \leftarrow S)$ is equivalent energy imparted per unit mass of the target organ, T, due to the disintegration of a specific radiation occurring in source organ, S, and is represented by the following equation:

$$S_W(T \leftarrow S) = \sum_i n_i E_i Q_i \text{SAF}_i(T \leftarrow S) \quad (4)$$

where $n_i E_i$ = mean energy emitted by radiation, i ; Q_i = quality factor for radiation, i ; $\text{SAF}_i(T \leftarrow S)$ = specific absorbed fraction of radiation, i .

Substituting into the equation for dose rate in a target organ, T, and summing over all sources, one obtains the first principles equation for the equivalent dose rate, $H_T(t)$:

$$H_T(t) = \sum_s A_s(t) S_W(T \leftarrow S) \quad (5)$$

To represent stochastic risk the dose quantities of equivalent dose, H_T , and effective dose, E, are used. Integrating the equivalent dose rate with respect to time commitment (typically taken to be 50 years for an adult) yields the equivalent dose in tissue T, after an intake at time t_0 , as follows:

$$H_T = \sum_s \int_{t_0}^{t_0+50} A_s(t) S_W(T \leftarrow S) dt \quad (6)$$

Equivalent dose and effective dose are expressed in terms of the sievert (Sv), or rem, which implies that the relative biological effects have been taken into account. According to the recommendations made by the International Commission on Radiological Protection (ICRP) in Publication 103, effective dose is the tissue-weighted sum of the equivalent doses in all specified tissues and organs of the human body and represents the stochastic health risk to the whole body (ICRP, 2007). Thus, effective dose is defined as follows:

$$E = \sum_T w_T H_T = \sum_T w_T \sum_R w_R D_{T,R} \quad (7)$$

where w_T = appropriate tissue weighting factor; H_T = equivalent dose to an organ or tissue; w_R = appropriate radiation weighting factor; $D_{T,R}$ = absorbed dose in tissue, T, by radiation, R.

Further, the protection quantities of effective dose and equivalent dose are defined using mathematical models such as the anatomical and physiological parameters of Reference Man detailed in ICRP Publications 23 and 89 (ICRP, 1975, 2002). Reference Man provides the foundation for the biokinetic models that describe how radioactive materials are transported and retained within the human body. Using these models, dose coefficients have been derived and tabulated in various compendiums, such as ICRP Publications 68 (ICRP, 1994b), 72 (ICRP, 1995), and 119 (ICRP, 2012), which can be utilized to calculate effective doses once an internal deposition has been ascertained.

Internal dosimetry parameters and models

Several important factors influence internal dose estimation and the impacts of these factors should be understood. First, when assessing internal dose, the dosimetrist should establish the exposure scenario. Second, the physicochemical properties of any internally deposited radioactive materials should be characterized to determine their impact on the movement of material throughout the body. Finally, the dosimetrist should have a basic understanding of the types of computational models involved and how they work together.

The exposure scenario determines the time involved and how the material entered the human body. As far as entry into the body, there are multiple pathways providing routes of entry. Inhalation and ingestion are routes of intake, and entrance into the bloodstream or absorption through the skin is referred to as an uptake. As for the time involved in the exposure scenario, there are two possibilities – acute exposure or chronic exposure. Chronic exposure occurs over an extended period and an acute exposure occurs all at once. In reality, chronic exposures can be quite complex often involving multiple acute exposures superimposed on an underlying continuous exposure. An acute exposure typically can be traced back to a specific event such as a fire involving airborne radioactive material. If a worker was in the area at the time of the fire and sustained an inhalation intake before evacuating the area, this would be considered an acute inhalation intake. On the other hand, a chronic exposure typically involves daily routine work with low-levels of airborne radioactive material. An example would be a worker that enters radiological areas on a daily basis and performs hands-on work with radioactive material. This type of worker has the potential to sustain small inhalation intakes each day that are continuous and build up over an extended period of time and this type of intake is called a chronic intake.

The radioactive material involved makes an impact on the overall internal dose estimate, so it is important to characterize the work area to identify and understand what might be available as potential source material. Some material properties that are necessary are the chemical form of the material, which determines its solubility, and the aerosol size (known as activity median aerodynamic diameter (AMAD)). These factors are important because they impact the deposition and clearance of material in the human respiratory tract. Initially, in ICRP Publication 2 (ICRP, 1959), the lung model was a two-compartment model consisting of the upper respiratory tract and the lower respiratory tract. ICRP Publication 30 (ICRP, 1979) adopted a multi-compartment lung model consisting of the nasopharyngeal (NP), tracheobronchial (TB), pulmonary (P), and lymphatic (L) regions which classified material according to clearance through the lung as shown in Fig. 1. The large arrows in the figure represent the deposition (D) into each region of the lung (30% in the NP region, 8% in the TB region, 25% in the P region, with the remainder being exhaled) and the smaller arrows indicate the fraction of the material, F, that leaves each compartment with an associated clearance half-time, T, specified in days. The three solubility classes considered with this lung model involve clearance times from the pulmonary region on the order of days, weeks, and years—Class D, W, and Y.

The updated lung model in ICRP Publication 66 (ICRP, 1994a) classifies material in terms of the transfer to the blood with the mechanical clearance being independent of chemical form. Thus, radioactive material clearance, or how it is being transferred to the blood, is now described as either fast, medium, or slow - Type F, M, or S. The ICRP Publication 66 lung model incorporates current knowledge of the morphological, physiological, and radiobiological characteristics of the human respiratory tract. Fig. 2 shows the compartments in which inhaled particles may be deposited. As shown in this figure, the lung is divided into the following compartments: anterior nasal passages (ET₁), naso-oropharynx/larynx or posterior nasal passages (ET₂), bronchi (BB), bronchioles (bb), and alveolar interstitium (AI). The anterior nasal passages account for the removal of material via extrinsic means such as nose blowing. The naso-oropharynx/larynx region accounts for material that is assumed to be swallowed, passed into the GI tract, and excreted in the feces. The bronchi, bronchioles, and alveolar interstitium make up the thoracic region. Depositions in the thoracic region are transported to the blood through absorption, to the GI tract by mechanical processes, and to the lymph nodes. Material that is absorbed in the blood is passed through the kidneys and bladder and ultimately excreted via the urine pathway.

In addition, as shown in Table 1, the aerosol size affects the lung deposition and clearance because finer particulates deposit deeper into the lung and clear more slowly than larger particulates deposited in the upper airways. The chemical form of the material determines its solubility and the ultimate uptake into the blood for biological processing through the body. More soluble materials (Types F and M) are rapidly cleared from the lung and preferentially excreted in the urine whereas insoluble materials (Type S) are more slowly cleared and excreted in the feces. For occupational exposures the default value recommended for the Activity Median Aerodynamic Diameter (AMAD) is 5 μm , which is considered to be more representative of workplace aerosols than the 1 μm default value adopted in ICRP Publication 30 (Dorrian and Bailey, 1995).

To derive internal dose estimates, the parameters of Table 1 are incorporated into computational models describing the movement of radioactive material throughout the human body. The intake models describe the movement of material through the lung and gastrointestinal tract. The systemic models describe how the material is absorbed into the bloodstream and its distribution of the uptake throughout the body. The excretion models describe how the material is processed and excreted from the body via the urinary and fecal pathways. Ultimately, these models work together as shown in Fig. 3, by incorporating the various material and exposure parameters to result in an overall dose consequence from internally deposited radionuclides.

Before being able to apply the readily available dose coefficients to convert intake into internal dose, the intake has to be estimated. These intake estimates can be accomplished either by using observed air concentrations or through bioassay measurements.

Fig. 1 Mathematical model used to describe clearance from the respiratory system. The values for the removal half-times, T, and compartmental fractions, F, are given in the tabular portion of the figure for each of the three classes of retained materials. The values given for D_{N-P} , D_{T-B} and D_P (left column) are the regional depositions for an aerosol with an AMAD of 1 μm . The schematic drawing identifies the various clearance pathways from compartments a-i in the four respiratory regions, N-P, T-B, P, and L. Reproduced with permission from Figure 5.2 in ICRP (1979) Limits for intakes of radionuclides by workers, ICRP Publication 30, Part 1. *Annals of the ICRP* 2(3/4). Oxford, UK: Pergamon Press.

Fig. 2 Schematic showing the respiratory tract compartments in which material can be deposited in the ICRP Publication 66 lung model. Obtained from Figure 7 in ICRP (1994a) Human respiratory tract model for radiological protection, ICRP Publication 66. *Annals of the ICRP* 24 (1–3). Oxford, UK: Pergamon Press.

Table 1 The effect of particle size on regional deposition within the lung of inhaled aerosols.

Region	Aerosol AMAD	
	1 μm	5 μm
ET ₁	16.52%	33.85%
ET ₂	21.12%	39.51%
BB	1.24%	1.78%
bb	1.65%	1.10%
AI	10.66%	5.32%
Total	51.19%	81.96%

NOTE: Fractional deposition based on use of the recommended default values for describing the physical characteristics (e.g., particle density of 3 g/cm³, etc.) of the involved aerosol.

ICRP (1994b) Dose coefficients for intakes of radionuclides by workers – Replacement of ICRP Publication 61, ICRP Publication 68. *Annals of the ICRP* 24 (4). Oxford, UK: Pergamon Press.

Air concentrations can be measured using several types of air sampling devices such as low-volume air samplers, high-volume air samplers, continuous air monitors, and lapel air samplers. Refer to ANSI N13.56 for a more detailed discussion concerning the different types of air sampling devices (ANSI, 2019). Using the air concentrations measured by these devices, the intake activity can be determined by multiplying the air concentration by the individual's breathing rate and duration of the exposure. When using bioassay measurements to estimate the intake activity, there are two categories of bioassays to consider—direct bioassay (also called *in-vivo* bioassay) and indirect bioassay (also called *in-vitro* bioassay). As can be inferred by the name, direct bioassay techniques measure the activity present in the body, whereas indirect bioassay techniques infer the activity based on measurement of excreta. Whole body counts, lung counts, thyroid counts, and scanning bed counts are examples of direct bioassay techniques. Urinalysis and fecal analysis are examples of indirect bioassay techniques.

To illustrate the concepts of intake estimation and calculation of dose consequence, consider the following example:

A worker spends time in an area where Co-60 oxide is present. The physical half-life, $T_{1/2}$, for Co-60 is 5.271 years. At the end of the quarter, the worker submits their routine urine bioassay (70 days after a suspected exposure) and activity is detected in his sample. Additional urine sampling indicated the following excretion pattern:

Fig. 3 Routes of intake, transfers, and excretion. Reproduced from Figure 1 in ICRP (1977) Recommendations of the International Commission on Radiological Protection, ICRP Publication 26. *Annals of the ICRP* 1(3). Oxford, UK: Pergamon Press.

Days after suspected exposure	24-h Urine activity (Bq)
70	60
100	50
130	45

In addition, the worker had a lung count performed on day 70 and the result was 0.25 MBq of Co-60.

Step 1: For this example, look up the intake retention fractions based on the system of models from ICRP Publication 68 for Type S Co-60 (oxide) tabulated by [Potter \(2002\)](#).

Time post suspected intake (days)	Fraction of initial intake In:	
	24-h Urine	Lung
70	2.06E-05	4.02E-02
100	1.50E-05	n/a
200	7.53E-06	n/a
130 ^a	1.16E-05	n/a

^aNOTE: A log-log interpolation was performed between 100 and 200 days to obtain the value at 130 days.

Step 2: Perform point estimates of the intake for each type of assay. If the estimates for each type are consistent then their average is the overall estimated intake. If they are not consistent, re-evaluate the assumptions (e.g., chemical form, route of intake, etc.) to determine if there may be a problem. A good rule of thumb when determining consistency is if the intake estimates are within a factor of two.

Point estimates of the intake are determined using the following equation:

$$\text{Intake} = \frac{R}{\text{IRF}(t) * e^{-\lambda t}} \quad (8)$$

where R = bioassay result; IRF(t) = expected fractional activity in the bioassay result at time t per unit intake, $\lambda = \frac{\ln(2)}{T_{1/2}} = 3.60\text{E-}04 \text{ d}^{-1}$.

Intake estimates based on urine results				
Time (days)	Urine results (Bq)	IRF(t)	$e^{\lambda t}$	Intake (MBq)
70	60	2.06E-05	0.975	2.99
100	50	1.50E-05	0.965	3.45
130	45	1.16E-05	0.954	4.07
Intake estimates based on lung count results				
Time (days)	Lung count results (MBq)	IRF(t)	$e^{\lambda t}$	Intake (MBq)
70	0.25	4.02E-02	0.975	6.36

Averaging the three estimated intakes based on urine sampling results in an intake estimate of 3.50 MBq. Combining the average intake estimate from the urine data with the intake estimate based on the lung count data yields an overall intake estimate of 4.94 MBq.

Step 3: Use one of the compendiums of dose coefficients to look up the inhalation dose coefficient for Type S, 5 μm AMAD, Co-60. Applying the dose coefficient of $1.7\text{E-}08 \text{ SvBq}^{-1}$ from ICRP Publication 68 results in an effective dose for the worker in this example of 0.084 Sv or 84 mSv.

Since there are multiple data points associated with the urine bioassay technique in this example, further refinement of the intake estimate can be achieved by applying the method of least squares to evaluate the data. Unweighted least squares fitting estimates the unknown parameters by minimizing the sum of the squared deviations between the data and the model as follows:

$$I = \frac{\sum_i R_i \text{IRF}(t_i)}{\sum_i [\text{IRF}(t_i)]^2} \quad (9)$$

Weighted least squares fitting can be used in the case where there is a high degree of variability between the precision of the data points to properly reflect the behavior of random errors in the data model as follows:

$$I = \frac{\sum_i R_i}{\sum_i \text{IRF}(t_i)} \quad (10)$$

Because there were multiple data points for the urine bioassay in the example, utilizing the intake equations for both the unweighted and weighted methods together with the data in the table below demonstrates the effect of least squares fitting when estimating the intake.

Time (days)	Urine result (Bq)	IRF(t)	$R^* \text{IRF}(t)$	$\text{IRF}(t)^2$
70	60	2.06E-05	0.00124	4.24E-10
100	50	1.50E-05	0.00075	2.25E-10
130	45	1.16E-05	0.00052	1.34E-10
Totals:	$\Sigma R = 155$	$\Sigma \text{IRF}(t) = 4.72\text{E-}05$	$\Sigma R^* \text{IRF}(t) = 0.00251$	$\Sigma [\text{IRF}(t)]^2 = 7.83\text{E-}10$

With the unweighted least squares method, using Eq. (9) and the values from the table above, the intake based on the urine data in our example is estimated to be 3.21 MBq. With the weighted least squares method, using Eq. (10) and the values from the table above, the intake is 3.28 MBq. Multiplying the estimated intake activity by the dose coefficient of $1.7\text{E-}08 \text{ SvBq}^{-1}$ (from Step 3 in the example) results in the following effective dose estimates for our worker: (a) for the weighted intake, the effective dose is 0.056 Sv, and (b) for the unweighted intake, the effective dose is 0.054 Sv. No matter what method was selected to estimate the intake in this example, the results were similar. The annual dose limit of 0.05 Sv was exceeded and further bioassays will be needed to refine and finalize the internal dose for this worker.

Operational internal dosimetry

What makes a good internal dosimetry program? The fundamental goals of a good program should be to monitor workers appropriately for internal depositions of radionuclides and to assess and record the resultant internal doses from these depositions. The first step in achieving these goals is to characterize the workplace to identify what radionuclides are present, and to determine their chemical forms and other characteristics, which might affect internal dose assessments, such as particle size and potential intake routes. Bioassay is integral to being able to determine the time and amount of internal radionuclide depositions. Therefore, it is important to use the right types of bioassay and to assign the best scheduling frequencies to achieve the operational goals of the

program. There are two main categories of bioassay—routine and special. Routine bioassay samples are needed to ensure that administrative and engineering controls are working as intended and they are scheduled at pre-determined frequencies. Special bioassay samples are scheduled at the direction of an internal dosimetrist and are needed to confirm an internal deposition has occurred or to provide follow-up information for an internal deposition that has already been confirmed.

When determining the types of bioassay to implement within an internal dosimetry program consideration should be given to the source radionuclides and the detection limit associated with each bioassay type. The type of bioassay chosen should be capable of detecting an intake at the suggested monitoring level for internal doses from applicable regulatory guidance. However, at the very least, the type of bioassay chosen has to provide evidence of compliance with the regulatory dose limits. As stated in ANSI N13.39, “Design of Internal Dosimetry Programs”, the critical point of administering a routine bioassay program is to find the balance between satisfying detection objectives and avoiding unnecessary monitoring (ANSI, 2011). At the Y-12 National Security Complex, one way we have accomplished this balance is to utilize Radiological Work Permits (RWPs) to convey the bioassay requirements from our workplace characterization efforts. RWPs are used to initiate routine bioassay scheduling instead of defaulting to a set frequency for monitoring independent of radiological work. The RWP logins are captured electronically and transferred to the scheduling system where scheduling is initiated for an individual only after they have signed in on an RWP requiring bioassay. The required bioassay appointment is then scheduled at a prescribed frequency (e.g., quarterly, monthly, or bi-monthly). The individual can then continue to use RWPs as often as necessary and they will not be scheduled for additional bioassay appointments until after submission of the initial required appointment. This type of scheduling can significantly reduce the number of unnecessary bioassays by only scheduling when triggered by RWP use.

The concept of minimum detectable dose (MDD) is used when determining the appropriate default frequency for scheduling routine bioassay measurements. Minimum detectable dose is an estimate of the internal dose that could go undetected between scheduled routine bioassay measurements. For a single acute inhalation intake, the greatest minimum detectable dose will occur when the most recent bioassay result equals the minimum detectable activity (MDA) of the analytical technique and the intake occurred just after the previous bioassay submittal. The minimum detectable dose for a single acute intake is calculated as follows:

$$MDD = \frac{MDA}{IRF(t)} \times DC \quad (11)$$

where MDD = minimum detectable dose; MDA = minimum detectable activity of the analytical technique; IRF(t) = intake retention fraction for the appropriate radionuclide at time, t, post intake; DC = dose coefficient (earlier referred to as the dose conversion factor).

For a chronic inhalation intake, the assumption is that the individual sustains a fraction of the overall intake each day over an extended period. Since the intake is continuous, the amount of radioactive material observed in a given compartment will increase with time until it reaches equilibrium with the intake rate. Similar to the acute intake scenario, the greatest minimum detectable dose occurs when each bioassay result throughout the exposure period equals the minimum detectable activity level for the analytical technique. For this case, the minimum detectable dose is given by the following:

$$MDD = \frac{A(t)}{IRF(t)} \times DC \quad (12)$$

where MDD = minimum detectable dose; A(t) = activity observed in a given bioassay at some time, t; IRF(t) = fraction of the total intake since exposure began until time, t; DC = dose coefficient (earlier referred to as the dose conversion factor).

As an example of the minimum detectable dose concept, consider the values shown in the table below for Americium urine bioassay. The intake profile is based on the absorption type of the material (Fast (Type F), Medium (Type M), or Slow (Type S)), the particle size of the material (typically 5 µm for occupational intakes), and the type of intake/uptake. The activity in the urine bioassay for this example is given in terms of disintegrations per minute (dpm) observed in a 24-h sample. The tabulated values are the expected minimum detectable internal doses per observed urinalysis result specified in units of $mrem \cdot dpm^{-1}$. If the analytical laboratory states that their minimum detectable activity for Am-241 urinalysis is 0.1 dpm, selecting a monthly frequency of participation would result in the following minimum detectable dose values: 172 mrem for an acute inhalation scenario, 42 mrem for a chronic inhalation scenario, and 258 mrem for an acute ingestion. In this example, to be able to detect a 100 mrem internal dose, either the MDA needs to be lower, the scheduling frequency needs to be shorter, or one should consider adding fecal sampling in addition to urinalysis to achieve the goals.

		Time post Intake (days)						
Intake profile ^a		7	14	30	60	90	180	365
Acute Inhalation (5 µm)	Type M	783	1110	1720	2410	2870	4120	6460
Chronic Inhalation (5 µm)	Type M	132	232	416	697	923	1460	2300
Acute Ingestion	f ₁ = 5E-04	515	957	2580	4900	5660	6880	8200

^aNOTE: For reference, the recommended absorption type (e.g., Type M) and gastro-intestinal absorption fractions (f₁), can be found in publications like ICRP Publication 78 (ICRP, 1997).

As you can see by the variability of the dose numbers in the table for minimum detectable dose, the default assumptions are important and can have great impact on the overall dose consequence. This is why the default assumptions should be documented for each area of the facility. Guidance on the selection of appropriate monitoring techniques and assumptions regarding the intake profiles for specified radionuclides are in publications like ICRP Publication 78 (ICRP, 1997).

In addition to determining the default exposure scenarios, reference levels should also be documented for the bioassay program. These reference levels are used to determine follow-up actions when the value of a quantity exceeds or is predicted to exceed the reference level (ICRP, 1988). Reference levels apply to both routine and special monitoring. According to ANSI N13.39, if there are choices for default assumptions to characterize the conditions applicable to a worker or set of workers, the default assumptions should be chosen to optimize the derived reference level (ANSI, 2011). There are different types of reference levels including the following: (a) the screening level which is the level below which a bioassay result does not need to be investigated and dose does not need to be assigned, (b) the verification level which is the level above which an effort should be made to confirm if an intake is real by invoking special bioassay protocols, (c) the investigation level which is the level requiring initiation of an investigation and special bioassay to help determine the conditions of exposure for the purposes of assessing dose instead of using default parameters, and (d) the medical referral level is the level at which medical staff at the facility should be notified. Fig. 4, obtained from ANSI N13.39, demonstrates how to use these reference levels.

According to the guidance provided in ANSI N13.39, workers should participate in a routine bioassay program if they have the potential to incur an intake at the investigation level specified in the applicable regulatory requirements or if respiratory protection is used to limit exposure potential in the workplace. When determining potential, one must consider both existing conditions and conditions that could occur due to a loss of control in the workplace. The success of any monitoring program depends on the workers and if they do not submit their scheduled *in-vitro* samples on time or show up for scheduled *in-vivo* counts then the accuracy of the program is impacted. Therefore, it is important to have administrative policies in place to ensure compliance with documented bioassay requirements. At the Y-12 National Security Complex, individuals are given a grace period of 2 weeks to submit requested bioassay samples which allows them flexibility in their schedule to collect the samples. The individual is sent a notice to remind them of the need for sample submission when their sample is 10 days past due. If the individual does not submit the requested sample by the 15th day past the scheduled appointment date, or if they do not show up for a scheduled lung count,

Fig. 4 Flowchart demonstrating the use of reference levels when evaluating bioassay results. Reproduced with kind permission from ANSI/HPS N13.39-2001(R2011), "Design of Internal Dosimetry Programs".

they are restricted effectively preventing them from performing work in radiological work areas governed by RWPs. This type of administrative policy encourages workers to submit their samples on time to avoid restriction.

Even with timely submission of requested bioassay samples, other factors can greatly influence an internal dose assessment. Therefore, all the assumptions utilized in a dose assessment need to be thoroughly documented. If an acceptable fit to the bioassay data cannot be obtained, then additional attempts can be made by changing assumptions. Examples of the assumptions to be changed include the following: (1) the exposure scenario, (2) the intake mode, (3) the solubility of the material, (4) the particle size of the material, and (5) the deposition and metabolic parameters in the biokinetic models. In addition, one could discount an outlying result or exclude interferences from prior intakes or non-occupational exposures.

As an example of how to characterize the work area and document modification of one of the parameters affecting internal dose estimation, consider the material solubility parameter and its effect on internal dose calculations at the Y-12 National Security Complex. A study conducted at Y-12, selected several radiation workers as representative of the site and scheduled them for special bioassay. Each worker submitted paired urine and fecal bioassay samples, and as instructed, collected the samples on or about the same date. The analysis of the data set provided an indicator of the solubility of the uranium involved with different operations at the site. From this study, Y-12 observed that the urine and fecal data were not consistent with older ICRP models (e.g., ICRP Publications 30 and 54). The older models indicated a fecal to urine ratio that was smaller than observed. The data from this study confirmed that the newer models of ICRP Publication 78 were consistent with the Y-12 observations as documented in ORNL/TM-114 (Eckerman and Kerr, 1999). Fig. 5 demonstrates this fact in the panel that compares Class Y and Type S urinary and fecal excretion.

Therefore, if urine and fecal data are available, the solubility mixture can be determined by calculating independent estimates of the intake rate based on urine and fecal samples using the newer ICRP models specified in ICRP Publication 60 and later. When evaluating the bioassay data submitted by individuals whose exposure potential is with insoluble uranium, one should expect that the urine and fecal data would produce similar estimates of intake. If the intake rates derived from the urine data, assuming Type S uranium, are significantly larger than those based on the fecal data, then the exposure may involve a mixture of Type M and Type S uranium. The calculations will then determine what fraction of the intake rate is attributable to Type M uranium using

Fig. 5 Expected 24-h urinary and fecal excretion of uranium following an acute intake using the models of ICRP Publication 54 with an AMAD of $1\ \mu\text{m}$ and ICRP Publication 78 with an AMAD of $5\ \mu\text{m}$. Obtained from Figure 6 in ORNL/TM-114.

Eq. (13) below, such that the intake rate predicted by evaluating the urine data with the assumed solubility mixture, will agree reasonably well with the intake rate indicated by the fecal data alone.

$$f_M = \frac{\frac{1}{\langle I \rangle} \sum_i^{N_u} A_u(t_i) - \sum_i^{N_u} E_u^S(t_i)}{\sum_i^{N_u} E_u^M(t_i) - \sum_i^{N_u} E_u^S(t_i)} \quad (13)$$

where f_M = fraction of the intake rate attributable to Type M uranium; $\langle I \rangle$ = intake rate; N_u = number of urine samples; $A_u(t_i)$ = Activity observed in the i th urine sample at time t_i ; $E_u^S(t_i)$ = Estimated activity, assuming Type S, in the i th urine sample at time t_i ; $E_u^M(t_i)$ = Estimated activity, assuming Type M, in the i th urine sample at time t_i .

The conclusion of this study was that the method of determining the solubility based on the fraction of uranium intake was a more stable index of uranium exposures at the site than using the older methods. It also resulted in the development of a new internal dosimetry code, DOSE68, that implemented the ICRP Publication 60 recommendations at Y-12.

Software for internal dosimetry

The internal dosimetry computational framework has advanced as a result of input from the National Council on Radiation Protection and Measurements (NCRP), the International Commission on Radiological Protection (ICRP), and the Medical Internal Radiation Dose (MIRD) committee of the Society of Nuclear Medicine. Currently, a common mathematical formulation has been achieved within the nuclear medicine and radiation protection communities (Loevinger and Berman, 1968, 1976). This status of the mathematical modeling of physical, anatomical, and biological processes has been achieved due to advanced computer hardware. Two early software packages noting the capability of micro or personal computers in internal dosimetry were Killough and Eckerman (1984) and Birchall and James (1989).

In 1977, the ICRP issued revised radiation protection guidance in Publication 26 (ICRP, 1977). The secondary quantities and dose coefficients based on this guidance were released in 1979 in ICRP Publication 30 (ICRP, 1979). The dosimetric data were computed at Oak Ridge National Laboratory on a mainframe computer (Watson and Ford, 1980). The set of coupled first-order differential equations describing the behavior of the radionuclide and its progeny within the body was solved numerically. Software initially developed for the MIRD committee was used to tabulate the nuclear decay data (Dillman et al., 1975; Dillman, 1980), and this data was later issued in ICRP Publication 38 (ICRP, 1983). Similarly, the anatomical model developed within the MIRD committee was used to derive the photon specific absorbed fraction to enable assessment of the absorbed dose in a tissue resulting from nuclear transformations occurring in other organs. With emerging micro and personnel computers, the IREM code was developed independent of the mainframe code (Killough et al., 1978). At this time, the ICRP did not address dose coefficients for members of the public.

In 1990, the ICRP revised its primary radiation protection guidance. It was noted that many radioactive compounds cleared from the lung in a manner different from the Days (D), Weeks (W), or Years (Y) classification of the Task Group Lung Model used in ICRP Publication 30 (Bates et al., 1966). Thus, ICRP Committee 2 updated the respiratory tract model and published the details in ICRP Publication 66 (ICRP, 1994a) with the uptake rate to blood (absorption) classified as F (fast), M (medium) and S (slow). The corresponding dose coefficients for occupational exposure were derived by an ICRP Task Group and appeared in ICRP Publication 68 (ICRP, 1994b).

The ICRP also began developing dose coefficients for members of the public in Publication 56 (ICRP, 1990) with a final summary in Publication 72 (ICRP, 1995). The need for such coefficients was highlighted by the Chernobyl accident in 1986. An international team of experts carried out the derivation of these coefficients using several independent computer codes. One member of the ICRP team employed an eigenanalysis solver (Fell et al., 2007). Another code used in these derivations was the DCAL computer code (Eckerman et al., 2008). Following completion of the ICRP tasks, the U.S. Environmental Protection Agency (EPA) freely distributed the DCAL code. The system of differential equations is solved within DCAL as discussed by Leggett et al. (1992) and Eckerman et al. (2008). The DCAL software was also used to derive the risk coefficients of Federal Guidance Report 13 (U.S. EPA, 1999).

Currently ICRP Committee 2 is deriving dose coefficients of occupational and environmental exposures that are consistent with the primary radiation protection guidance of ICRP Publication 103 (ICRP, 2007). This ongoing work has appeared in ICRP Publications 130, 134, 137, and 141. This work implements the human alimentary tract model of ICRP Publication 100 (ICRP, 2006), the anatomical model of ICRP Publication 110 (ICRP, 2009), the updated nuclear decay data of ICRP Publication 107 (ICRP, 2008), the specific absorbed fraction data of ICRP Publication 133 (ICRP, 2016) and updated biokinetic models in which the behavior of progeny is independent of the parent's biokinetics. Presumably, the updated software will be released following completion of these efforts.

Numerical databases of dose and bioassay coefficients have been assembled and are generally distributed with a "viewer" software. The DFACT software available from Oak Ridge National Laboratory (<https://www.ornl.gov/crpk/software>) contains the dose coefficients for the radionuclides considered in ICRP Publication 30 (ICRP, 1979). ICRP also distributed a viewer containing the occupational dose coefficients of ICRP Publication 68 (ICRP, 1994b) and environmental dose coefficients of ICRP Publication 72 (ICRP, 1995). These dose coefficients and occupational bioassay coefficients as well as other radiation protection matters are

included in the Radiological Toolbox distributed by the Nuclear Regulatory Commission on the RAMP website (<https://ramp.nrc.gov/>). ICRP is now offering a viewer of the dose and bioassay coefficients recently published (ICRP, 2015, 2017a,b). Table 2 below lists the lung dose coefficients for occupational exposures in ICRP guidance over the past four decades. The Publication 30 clearance rates from the lung are noted in terms of Days (D), Weeks (W), and Years (Y) and characterize both the mechanical and absorption processes. The Publications 68 and 137 clearance rates refer to absorption (Fast (F), Medium (M), and Slow (S)) and reflect the chemical form of the material. Note Publication 137 includes six lung dose coefficients with specific guidance (see table footnotes) regarding chemical form.

There are two widely-used commercial software packages for estimation of a worker's intake based on observed bioassay data—Integrated Modules for Bioassay Analyses (IMBA) (Birchall et al., 2003) and ICRP's Internal Dosimetry Expert Analysis (IDEA) System (Doerfel et al., 2007). Both packages, IMBA (currently updated and renamed TAURUS) and the IDEA System, are being updated to merging ICRP guidance (ICRP, 2015, 2017a,b). There are, of course, institutional-specific software codes established to access bioassay databases and derive dose records to estimate a worker's annual dose. The ICRP 30 based DOSEXPRT software used in the 1990s in the Oak Ridge area, and the newer ICRP 60 based DOSE68 software currently in use at ORNL and Y-12 are such examples.

Applicable regulations and guidance documents related to internal dosimetry

In the United States, federal regulations convey the radiation protection requirements that provide the basis for occupational internal dosimetry programs. There are two main groups of facilities in the United States—those that fall under the purview of the Department of Energy (DOE)/National Nuclear Security Administration (NNSA) and those under the purview of the Nuclear Regulatory Commission (NRC). For NRC sites, the radiation protection requirements are in Title 10, Part 20 of the Code of Federal Regulations (10CFR20, 2016). For DOE/NNSA sites, the requirements are in Title 10, Part 835 of the Code of Federal Regulations (10CFR835, 2007). There is a fundamental difference in the radiation protection requirements used by NRC sites and those used by DOE/NNSA sites. The difference lies in their technical bases. The requirements related to internal dosimetry in 10CFR835 are based on the recommendations from ICRP Publication 60 (ICRP, 1991) and those in 10CFR20 are based on the older recommendations from ICRP Publication 26 (ICRP, 1977).

To assist with the implementation of the regulatory requirements the NRC provides technical guidance in the form of published Regulatory Guides. These Regulatory Guides provide additional details to NRC licensees on acceptable methods to achieve implementation of the NRC regulations. For reference, below is a listing of the applicable Regulatory Guides that pertain to internal dosimetry:

Table 2 Uranium lung committed dose coefficients (Sv/Bq).

As for the DOE and NNSA sites, additional guidance can be found in standards published by the American National Standards Institute (ANSI), which oversees standards and conformity assessment activities for the United States. For reference, a list of the standards related to internal dosimetry is included below:

1. ANSI N13.14, "Bioassay Programs for Tritium"
2. ANSI N13.22, "Bioassay Programs for Uranium"
3. ANSI N13.30, "Performance Criteria for Radiobioassay"
4. ANSI N13.39, "Design of Internal Dosimetry Programs"
5. ANSI N13.54, "Fetal Radiation Dose Calculations"
6. ANSI N13.56, "Sampling and Monitoring Releases of Airborne Radioactivity in the Workplace".

Future direction in internal dosimetry

The emerging ICRP internal dosimetry formulations explicitly address both males and females. However, the sex differences in dose coefficients are largely associated with anatomical differences and not reflected in the biokinetic models. Sex differences in the volume of air breathed may need to be considered when interpreting bioassay measurements. In addition, dose and bioassay coefficients are presented in ICRP publications for a number of updated chemical forms for each radionuclide instead of just the standard default formulations. As noted in [Table 2](#), ICRP Publication 137 now addresses six chemical forms of uranium and the lung clearance no longer needs to be defined in terms of the default Type F, M, and S parameters ([ICRP, 2017b](#)). Implementation of the new guidance in national regulations awaits completion of the ICRP series of publications. Continued advances in computer hardware will lead to further improvements in the internal dosimetry methodology. This includes advances in physiological-based biokinetic modeling, mesh-type reference computational phantoms, and implementation of more detailed bioassay procedures.

Introduction to radiological survey instrumentation

Although humans are not able to see, hear, feel or smell radiation; we are able to detect the presence of radiation provided the appropriate instrumentation is available. A facility operating within the conditions of its regulatory license should know exactly where its radioactive materials (RAM) are located. Under operational conditions, such facilities have appropriate radiological survey instrumentation for general monitoring purposes that could include environmental monitoring; work place monitoring such as surveying a lab bench or hood, a process area, or routine required surveys of RAM storage areas; and personnel safety monitoring. However, situations occur during the facilities operational lifetime—such as spills, leaks, past disposal practices, etc.—that may have led to contamination requiring remediation. When conducting decommissioning and decontamination (D&D) activities for license termination, RAM is removed from the site and residual contamination is identified and remediated such that the concentrations of any remaining contamination are quantitatively shown to be below the regulatory limits by direct measurements made using appropriate radiation survey instrumentation, by the radiological analyses of samples, or both (Vitkus, 2021).

It is critical to choose the right tool to identify contamination and for collecting the data required to demonstrate that any contamination levels satisfy personal protection, operational, or regulatory limits. Different forms and types of radiation require different types of radiation survey instrumentation. The instrumentation to consider includes that used for surveys of land areas, structural surfaces, and the laboratory systems used for sample analysis. Laboratory analysis of samples is necessary to quantify residual concentrations of those radionuclides that are either difficult or undetectable using field instruments. Instrumentation for personnel monitoring, air monitoring, and similar radiological protection considerations are also available but are not included within the discussions that follow.

Radiological detection systems generally rely on measuring the energy deposited within the active volume of the detector. Some detectors use material that emit light (scintillate) when the radiation deposits energy within the active volume. Other detectors use gas that is ionized when interacting with radiation; the ions are collected and result in an electronic pulse (Han, 2021). In general there are two components of the detection systems that may be either separate or integrated into a single package. The detector captures the interaction energy and is coupled to an instrument that provides a high voltage to the detector and then records the interaction as a count. The instrument connected to the detector is likely either a ratemeter or ratemeter-scaler. Ratemeters provide an instantaneous reading—e.g., counts per minute (cpm), micro-Roentgens per hour (μR hr⁻¹)—based on the amount of radiation absorbed over a short time interval. An analog needle or a digital readout is observed that will continuously change as radiation emissions are random events and are observed as fluctuating measurements, most notable at lower, background count levels. The meter may also have a speaker to allow the surveyor to listen to the audible clicks. Contamination meters referred to as ratemeter-scalers have a digital scaler mode which allow for quantifying the number of counts over a defined time period, generally between one-half to 10 min.

The type of radiation—alpha, beta, or gamma radiation or a combination thereof—helps determine the detection system used. The selected detection system also depends on the surveyed medium, whether land area, structures, equipment or other media. As such, the physical and radiological characteristics of RAM contamination at a site determines which type(s) of detectors, discussed in the following sections, are used for surveys.

Land area (surface soil) survey instrumentation

Land area radiological investigations, referred to as radiological surveys, are performed to identify where soil contamination may be present and, depending upon the concentrations may require posting or remediation. The survey is performed to locate anomalous areas where elevated count rates are observed above the detector's background response range and signals that contamination may be present. Background radiation is ubiquitous and therefore the detection systems have a continuous background response; commonly stated in units of cpm. Identified anomalies where count rates exceed a nominal background are further investigated to determine if the elevated detector response is simply the result of natural background variability, other physical factors, or is due to radiological contamination within the soil volume.

Qualitative gamma radiation scanning: Hand-held detectors

The most efficient land area surface soil survey method for identifying anomalies is surface scanning for gamma radiation, provided of course that potential radioactive contaminants include one or more gamma emitters. Surface scanning involves moving the detector just above the soil surface either by a surveyor walking over the area in systematic or random transects—referred to as a gamma walkover survey. The surveyor listens to the audio response—each radiation detection event results in an audible click for those survey instruments with integrated speakers—and if elevated counts are heard, the surveyor will pause and investigate. This investigation may consist of concentrated scanning of a defined area or collecting a surface soil sample and then checking the subsurface soil for elevated counts and possibly following that up with more sampling. This is an important point requiring edification. Although the scanning has been introduced as a “surface” scan, it is important to be aware that the detected photons could have originated from buried contamination. Surface scanning might be better referred to as surface volume scanning, because the gamma photons, depending on their energy, are able to penetrate several centimeters of soil and therefore be detected at the surface.

Depending on the site, these surface scans will typically cover hundreds, or more likely, thousands of square meters. For very large sites, arrays of detectors are sometimes mounted to a vehicle or cart and driven over the surface. Drones are also being introduced to carry detectors over surfaces (Hackett, 2021). These mobile systems rely on assessing collected data post-survey, normally via computer programs, to identify anomalies, rather than real-time by an individual listening to meter audio.

Surface scanning land areas for alpha or beta radiation is rarely practical for a variety of reasons that are outside the scope of this discussion, including the fact that the alpha and beta particles are either completely shielded by, or unable to penetrate thin soil layers. Alpha or beta measurements on land area soil, if performed, are likely to be limited to static measurements, meaning collecting a count rate measurement while holding the detector stationary directly on the soil surface or perhaps the surface of a sample of the soil.

The workhorse detector used for soil surface gamma scanning is the sodium iodide (NaI) thallium activated (Tl) scintillation detector seen in Fig. 1.

NaI(Tl) scanning systems in general use only provide the observed counts without identifying information as to what radionuclides are present. These systems are considered qualitative only, and require additional investigation when count rate anomalies are encountered. The investigation is likely to involve sample collection with laboratory analysis to identify specific radionuclides present and the activity concentrations in units of picoCuries per gram or Becquerels per gram.

This type of gamma radiation detector is constructed with a NaI crystal into which trace amounts of thallium have been incorporated as an activator. NaI(Tl) is used because it is one of the most sensitive material to x-rays and gamma rays, although there are

Fig. 1 Surveyors performing gamma radiation walkover survey using 5.1 cm × 5.1 cm NaI(Tl) coupled to ratemeter-scaler and GPS/data logging equipment.

other inorganic crystal types such as lanthanum-bromide (LaBr) and cesium-iodide (CsI) that are used in special applications. When gamma energy is deposited, the crystal material will scintillate, i.e., emit a pulse of light. The light is converted into an electrical signal and then, in order for the signal to be registered as a count, must be amplified by an attached photomultiplier tube (PMT). This detection and amplification package, schematically illustrated in Fig. 2, is contained within a hermetically-sealed metal housing which may be either configured as an external probe connected to a ratemeter or contained within a stand-alone meter, both types are shown in Fig. 3.

An example stand-alone meter is a μ R meter which measures exposure rates. This instrument has a small NaI(Tl) detector within a protective case that includes the electronics that supply the power to the detector and an analog readout of the real-time measurements. The structure/surface survey instrumentation section below provides additional information on ratemeters and ratemeter-scalers.

NaI(Tl) crystals are manufactured in common sizes, typically cylinders of 2.5, 5.1, or 7.6 cm (1, 2, or 3 in.) in height and diameter, although much larger crystals are manufactured for special applications. The larger the crystal volume the greater the gamma photon interaction probability is that a gamma photon that enters the volume of the crystal will deposit all of its energy and be recorded as a count. Therefore, detector sensitivity increases with crystal size, including the background radiation, which means the large crystals will have relatively high background counts.

Not all gamma photons are the same, meaning they have varying energies, and the NaI detectors are energy dependent. At very low energies, the gamma may not be able to penetrate the housing and interact with the crystal. As energy increases, not only will the photon enter the crystal, but is likely to interact and deposit all of its energy, and be registered as a count. The sensitivity increases with increasing energy up to a point, when the higher energy photons may escape the crystal and sensitivity begins to decrease with increasing energy. Fig. 4 illustrates this concept for different sizes of gamma detectors.

Fig. 2 NaI detector schematic.

Fig. 3 NaI with ratemeter-scaler (left) and μ R meter (right).

Fig. 4 Comparative energy response curves for NaI(Tl) detectors (unlabeled curves are computer modeling results).

Specialty and semi-quantitative gamma radiation detectors

Radiation detection applications can take advantage of the energy dependent response illustrated in Fig. 5. Detector modifications such as crystal geometry, additional shielding, or electronic discrimination can be used to focus detection on specific energy regions, referred to as regions of interest, or ROIs of the energy spectrum. Radionuclides emit characteristic gamma rays that are consistent in both energies (measured in kiloelectron volts, keV) and the abundance. Where abundance is, the fraction of decays that result in a characteristic photon. Therefore, specific radionuclides can be identified and quantified by knowing (1) the energies of the photons, (2) the abundance of the specific gamma emission, and (3) the gamma detector efficiency at a given energy. More on that later.

There are physical and logistical constraints to consider when selecting the right detector for the job. Detectors with large crystals, although more sensitive, are heavy to carry during a walkover survey, and often require a cart or other mode of transportation. Fig. 5 shows a custom-made NaI(Tl) gamma detection system. The case contains two 6-in. (15.2 cm) by 6-in. (15.2 cm) NaI(Tl) detectors that are coupled to a ratemeter. The case is attached to a cart due to the size and weight of the system.

Another specialty detector is the FIDLER. The FIDLER (field instrument for the detection of low-energy radiation) has a large-area but very thin crystal. This particular detector was made to be sensitive to the low-energy x-rays emitted by Pu-238 as well as other low-energy emissions from some other radionuclides. Because of the thin crystal, higher energy photons will pass through without interacting. However, crystal geometry is not all that is required as the typical metal housing would have blocked the low-energy photons that the FIDLER is designed to detect. Therefore, the design includes a very thin window that the low-energy photons are able to penetrate, as illustrated in Fig. 6.

Vehicle mounted plastic scintillators

An alternative to NaI(Tl) detectors are plastic scintillators made from organic scintillating molecules that are suspended in a solid polymer base. Relative to NaI(Tl), plastic scintillators are much less expensive and can be manufactured in most any size or shape. The plastic scintillators are commonly used for applications where very large detectors are required. The detectors are configured in an array and either mounted directly to vehicles or towed behind. They are also found in fixed systems, such as a portal monitor where vehicles drive between what is normally two banks of detectors, one on either side. These large detectors are quite sensitive and if configured appropriately, are able to identify a specific region of a tractor-trailer or other load that is exhibiting elevated direct radiation levels and may require investigation. The disadvantage of the plastic scintillators is that the photon energy resolution is much less than that of the NaI(Tl) making them generally unsuitable for spectroscopic applications.

Peripherals

Surprisingly, there has been very little change in detector technology over the decades since radiation measurement systems were developed. Most technology advances have been in the peripherals, primarily miniaturization of the electronics that are coupled

Fig. 5 Encased cart-mounted large volume NaI(Tl) detector array coupled to GPS system.

Fig. 6 FIDLER gamma radiation detector.

to the detectors and software development. Important advances are the global positioning systems (GPS) and data logging systems which enable exceptional radiological investigation documentation. Until these systems became common place, survey data over large land areas consisted of a hand-written notes and annotated hard-copy maps. The surveyor might note the general observed count rates and whether any anomalies were identified and investigated. Data loggers now electronically record count rate data and geographic reference position every 1 or 2 s. So rather than a hand-written notes, there can be thousands of individual data points available as survey documentation. These data are then managed using computer systems and specific software to illustrate the results of the survey. In most cases, the data are presented as color-coded dots superimposed on an aerial photograph of the site. With the color-coding, anomalies should be readily identifiable to show contamination or conversely, the illustrate the absence of contamination as evidence stakeholders in a final report showing that a site has been adequately decontaminated. Fig. 7 is an example image of the data collected from a land area with two buildings present. The blue, green, and yellow shades illustrate variable background gamma radiation levels that are due to the varying concentrations of naturally occurring radioactive material (NORM) in different soil types present. Count rates of suspected anomalies are identifiable in orange, red, and magenta. This color coding, noting that red and magenta indicate the highest count rates, suggests contamination surrounding the building and at isolated locations seen as small red areas in both the upper and lower left-hand side of the Fig. 7. Contamination? Such locations would be investigated, possibly sampled for laboratory analysis, and if found to be contamination, would be addressed. The analysis of samples collected showed there was no contamination in the soil around the building. Actually, the higher levels around the buildings were due to the higher NORM concentrations common to some types of brick. Samples collected from the isolated locations away from the buildings would also be necessary to determine if the anomalies were from NORM within rocks that were common to the area—or represented contamination.

Other peripherals can be added to the gamma radiation scanning or fixed position detectors and instrumentation that have capability to perform spectroscopic analysis in real-time, possibly avoiding or greatly reducing the need for sample collection and

Fig. 7 Gamma radiation walkover scan data.

analysis. Such systems, discussed later, might include electronics and software to take advantage of the signature gamma photons emitted by various radionuclides, including NORM, that resolve the gamma radiation scan data into ROIs for radionuclide identification.

Common structure/surface survey instrumentation

Thus far, discussions have focused on radiation detection instrumentation for investigations of land areas. Perhaps more relevant to the forthcoming discussion is the edification that the gamma radiation measurements observe photons emitted from the volume of the medium, not just the surface. This distinction is important because volumetric sources (e.g., soil or drummed materials) can emit enough gamma radiation to detect from a distance—the detector does not have to be in contact, but can be several centimeters, even meters from the source. When radiological contamination is spread over a thin layer (e.g., dust or spill residues) on a surface, gamma radiation measurement may not be ideal when the contamination levels are much lower than that seen in a volume. This is not to say that gamma scans of structural surfaces would not be performed, because they absolutely would in many cases. More importantly, the specific radionuclide contaminating the surface may not emit gamma radiation. Traditionally, surveys of structural or other surfaces are for alpha and/or beta radiation and the measurements are reported as alpha, beta, or total activity levels—in units of dpm 100 cm⁻² or Bq cm⁻² (disintegration per minute per 100 square centimeters or Becquerels per square centimeter)—for an individual or mixture of radionuclides. The detectors are held close to the surface because the air gap between the detector window and the surface may act as a sufficient shield for alpha and beta radiation. This is especially true for alpha radiation, which can travel only a few centimeters in air. Therefore, alpha and beta detectors are held about a centimeter or less from the source's surface.

Much like with land area surveys, there are many instrument choices, and sometimes the best instrument for the contaminant(s) in question is not obvious. **Table 1** describes common detectors used for structures/surfaces surveys; each has advantages and disadvantages, as will be discussed. The trick is finding the right detector(s) to address the project objectives and to ensure the detectors respond to the radiations of concern. Some variables to consider while selecting structures/surfaces survey instrumentation are:

- Surface area—if surveying large areas like walls and floors, the best selection may be the detector with the largest probe area (i.e., the physical surface area assessed by the detector). Conversely, tight spaces that cannot be physically reached by a larger detector, require the smallest detector area.
- The radiation type—does the contaminant emit alpha radiation, beta radiation, or alpha and beta radiation? Do the surveyors have to report different results for each radiation type which would require multiple instruments to ensure that all the necessary data are collected?
- Convenience and mobility—there are cases where a surveyor needs to work in difficult environments, such as working from a ladder or in a confined space, and cannot be bogged down with a lot of bulky equipment. In these cases, the surveyors may only want a single instrument that covers all bases, or a few instruments that are easy to maintain and use.
- Detection capability—if the most important survey objective is the ability to detect very low contamination levels, the options narrow quickly and the detector selection process is extremely important. The wrong selection can lead to poor data quality, false

Table 1 Comparison of common structural/surface survey instruments.

<i>Instrument</i>	<i>Relative α sensitivity</i>	<i>Relative β sensitivity</i>	<i>Probe Area^a (cm²)</i>	<i>Pros</i>	<i>Cons</i>
Geiger Mueller	Poor	Fair	15.5	Easy to use, small detector for collecting measurements in hard-to-reach spaces	Poor to fair detection capabilities; small surface area so small coverage
Alpha Scintillator	Better	N/A	100	Easy to use; convenient when specifically trying to measure α-only radiation	Works for α radiation only
Plastic Scintillator	Better	Better	100	Easy to use; responds to both α and β radiation	Cannot discriminate between α and β radiation; also responds to γ radiation which is problematic in high radiation areas
Dual Phoswich	Better	Poor	100	Easy to use; can switch between α and β measurements using single instrument	Convenience of having one instrument for α and β balanced by poor to fair detection capabilities
Gas Proportional	Best	Best	Hand-held: 126 Large-area floor monitor: 584	Best detection capabilities; responds to both α and β radiation	Requires P-10 gas and extra tubing; need different electronic setup for α and β measurements (might need multiple detectors)

^aLudlum Measurements, Inc. Model 44–9 Geiger Mueller; Model 43–93 dual phoswich; Model 43–92 alpha scintillator; Model 44–142 plastic scintillator; Model 43–68 gas proportional.

negative decisions—deciding that contamination is not present when in fact it is—or errors that lead to rework, misrepresentation of radiological conditions, and other negative consequences. Consider an example where personnel health and safety and limiting exposures is a primary objective. Misrepresenting the radiological conditions could lead to personnel being exposed to higher contamination levels than those planned for. Conversely, in the case of over-stating levels, unnecessary personnel protective equipment might be required that introduce complications from additional physical stress or the addition of costly engineering controls.

Before describing individual detectors, saying that detector will detect either alpha or beta radiation is a bit of a misnomer. It is more accurate to say that some instruments can detect either alpha, beta, or alpha-plus-beta radiation. Which ones depends on the specific detector and the detector configuration. For example, an alpha scintillator only measures alpha radiation (hence the name), while a GM detector responds to alpha (α), beta (β) and gamma (γ) radiation, although they are not very efficient for alpha and gamma. The surveyor cannot tell which radiation type resulted the GM's audible "clicks" without additional procedures to help discriminate radiation types. Some detectors like the gas proportional detector can be configured to discriminate radiation types—the gas proportional detector can be configured to respond to only alpha, only beta, or alpha-plus-beta radiation, as will be demonstrated.

Detectors are useless by themselves unless they are either integrated with an electronics package or connected via cable to a ratemeter-scaler which was introduced earlier when discussing land area detectors. The main purpose of the ratemeter-scaler is to: (1) provide the voltage necessary for the instrument to function (e.g., from batteries), (2) produce an audible response ("clicks") that suggest the presence or absence of contamination, and (3) display the detector's response so that surveyors are not solely reliant on the audible clicks. For example, approximately 900 V are required for a typical pancake GM to operate properly—this voltage is supplied by the batteries in the ratemeter-scaler. When the GM is used in a survey, the ratemeter-scaler will generate clicks through a microphone or headphone jack, where the rate of clicks (a.k.a., cpm) are proportional to contamination levels. A surveyor may be able to hear an increase in the count rate but will not be able to quantify that increase. Therefore, the ratemeter-scaler displays the count rate using digital and/or analog display. Consider this scenario:

A surveyor connects a GM to a ratemeter-scaler via a cable, turns the ratemeter-scaler on, and notes that the voltage is set at 900 V—perfect. The surveyor then begins a survey noting an ambient count rate of about 60 cpm—i.e. typical background for a GM detector—on the display and the intermittent random "click—click—click—click—click—click—" audible output. As the survey progresses, the surveyor hears an increase in the audible clicking rate, looks at the display, and sees that the rate has jumped to approximately 200 cpm. So, the ratemeter-scaler has provided the necessary voltage, the audible stimulus that caused the surveyor to take notice, and quantitative count rate from a potentially contaminated area.

All the detectors listed in [Table 1](#), with the exception of the dual phoswich detector, can be coupled to the same type of ratemeter-scaler. The discussions following [Table 1](#) emphasize the detector, not the ratemeter-scaler.

Geiger Mueller detector

Geiger Mueller detectors come in a variety of configurations including "pancake," end-window, and sidewall. Pancake GMs are among the most widely-used radiation detectors for contamination surveys, and are often coupled with alpha scintillators (discussed later) as "friskers"—scanning hands and feet or personal items before exiting a potentially contaminated area—for beta and alpha radiation measurements, respectively. [Fig. 8](#) illustrates an health physicist performing a contamination survey using a pancake GM detector. As shown in [Table 1](#), advantages of using GMs are that they are easy to use and the small surface area (15.5 cm²) allows for surveys in hard-to-reach places where larger (e.g., 100–126 cm²) instruments cannot fit. While advantageous for surveys of hard-to-reach areas, the small size can be a disadvantage when surveying large areas—small detector area means more time is required to scan the surface area. Finally, other detectors described later in this section are better for measuring beta radiation (the GM is rated as fair), and GMs are rated as poor for measuring alpha radiation. Therefore, surveyors may select a pancake GM for beta frisking, for performing routine measurements when a lightweight mobile instrument is needed, or for performing measurements in a hard-to-reach area; but different instruments are likely better for large area surveys (e.g., floors, walls, an entire room or rooms, etc.) or when more sensitivity is required.

Before evaluating the next class of detectors, other GM configurations should be considered: end-window and sidewall GM detectors. The end-window is functionally the same as a pancake, though the pancake is relatively flat with a handle for ease of use while the end-window is cylindrical shaped and does not have a handle. The side-wall GM includes a thin metal filter that reduces the number of low-energy gamma rays reaching the detector when in the "closed" position, so surveyors can collect measurements in the open and closed position to see what contributions are from beta and beta plus gamma, and are most often used for measuring exposure rates. It is also noteworthy that GMs detectors will over-respond to low energy gamma (e.g., <200 keV) without energy compensation. Energy compensated side-wall GMs are available sometimes called "hotdog" or "pickle" probes, and different designs are available to measure low exposure rates (i.e., $\mu\text{R hr}^{-1}$ range) to high radiation exposure rates (e.g., 1 R hr⁻¹).

Fig. 8 GM detector in use to survey lab work counter.

Zinc sulfide alpha scintillator

Zinc sulfide silver activated (ZnS(Ag)) scintillators are designed to measure only alpha radiation, which can either be limiting or handy, depending on objectives. If, for example, only alpha emitters, like thorium-230 or plutonium-239 are present, then all the surveyor needs is a ZnS(Ag). If the contaminant includes a beta component, and beta data are needed to meet project objective, then another instrument will be required. As mentioned in the previous discussion, ZnS(Ag) and pancake GMs are commonly paired to measure alpha and beta radiation, respectively, for frisking or performing routine surveys. There are other detectors more efficient than a ZnS(Ag) for measuring alpha radiation, meaning it is not the best for some situations, but the detector is easy to use, and sometimes it is important to know that the only response is due to alpha radiation.

Zinc Sulfides typically have a 50 to 100 cm² probe area and are suitable for large area scans, such as walls or large pieces of equipment. The sensitive part of the detector is covered by a thin aluminized Mylar[®] window. The Mylar[®] window must be thin enough to allow alpha particles through to the detector, but must also be effective at blocking out all visible light. These fragile windows must be tested for light leaks before each use, and should be protected while in storage or transport.

Plastic scintillator

Plastic scintillators include a thin layer of Mylar[®] over a thin plastic detector and are designed to measure beta radiation. However, plastic scintillators will also respond to alpha and gamma radiation, and cannot discriminate between radiation types. Therefore, the surveyor may need to know which contaminants are present and the radiation types emitted, to fully understand the nature of the response. Because plastic scintillators will respond to gamma radiation, and as noted earlier are sometimes used for land area gamma radiation surveys, it may be important to account for background radiation levels while performing surveys near, for example, drummed materials emitting non-trivial levels of gamma radiation. As with the other detectors discussed so far, surveyors may need another detector (e.g., a ZnS(Ag)) if it is important to quantify alpha and beta activity separately. Surveyors may also take advantage of detector's sensitivity to multiple radiation types. For example, contaminants like radium paint and thorium oxide emit alpha, beta, and gamma radiation, and plastic scintillators can improve detection capabilities over other instruments discussed here by responding to all these emissions. Fig. 9 illustrates a surveyor performing a surface scan using a hand-held scintillation detector. The technician in Fig. 10 is using a gas proportional detector to scan for radioactive contamination on the inside of a research reactor cooling water pump cover.

As shown in Table 1, plastic scintillators are ranked as "better" for alpha and beta detection, relative to the other detectors listed. It could be ranked as best overall for alpha radiation, except the specific gas proportional described later has a larger probe area

Fig. 9 Surveyors using a plastic alpha/beta scintillator.

Fig. 10 (A) Example of a hand-held gas proportional detector. (B) Technician scanning an object with gas proportional detector coupled to P-10 gas supply and ratemeter-scaler.

(126 cm^2) than the plastic scintillator (100 cm^2), giving the gas proportional certain practical advantages. The relatively large probe area and ease of use make plastic scintillators suitable for large area scan, such as walls or large pieces of equipment.

Dual phoswich alpha/beta detector

Imagine the versatility if a detector was available that combined both a $\text{ZnS}(\text{Ag})$ scintillator and a plastic scintillator, and then also included a toggle so that the surveyor could discriminate between the alpha, beta, and alpha-plus-beta response? Such a detector is available. A dual phosphor alpha/beta detector includes a Mylar[®] window, followed by a thin layer of $\text{ZnS}(\text{Ag})$ that is sandwiched to a plastic scintillator. A specialized ratemeter-scaler is required to be coupled to the detector. The ratemeter-scaler has a discriminator toggle switch that surveyors use to discern the radiation type or types of interest that are being counted. Beta particles are far less massive and overall much less energetic than alpha particles. In addition, the beta particles are able to penetrate further in a media, whether that media is air, a piece of paper, or, in this case the detector volume itself. The alpha particles will hit the $\text{ZnS}(\text{Ag})$ layer,

deposit all their energy and stop, while the beta particles will pass through the ZnS(Ag) layer and interact with the plastic scintillator portion of the detector. From an energy standpoint, think about the difference between dropping a pebble (beta) and a bowling ball (alpha) from a tower into a deep pool of water. The detector's electronics has two channels; one that can tell the difference between the "small ripple" and second that tunes into the "large splash" of energy that has been deposited. One switch setting is used to respond only to small pulses (beta); another switch setting is used to respond to only large pulses (alpha), and yet another switch setting is used to combine the pulses (alpha-plus-beta as well as some gamma). The big advantage is that surveyors only need one detector for measuring alpha and beta radiation—combined or individually—so one instrument checks several boxes:

- Relatively large (100-cm²) probe area—check
- Detects multiple radiation types with discrimination—check
- A convenient and mobile detector—check

There are a couple of disadvantages. The first is the need to acquire the specialized ratemeter-scaler and the second is a loss in detection sensitivity. Sensitivity is typically described in terms of efficiency, where efficiency is basically the fraction, in terms of percentage, of radioactive particles that are counted per the total number of radioactive particles that were emitted from the surface beneath the detector during a given unit of time. **Table 1** shows that the detector is rated as better for alpha and poor for beta efficiency, specifically low-energy beta particles. This means that in cases where it is important to find low levels of beta contamination, surveyors should probably leave the dual phoswich on the shelf. However, dual phoswich may fit the need if convenience and flexibility are desirable.

Gas proportional detector

The gas proportional detector includes a Mylar[®] window and requires a continuous flow of P-10 gas (10% methane, 90% argon) to operate. The gas is supplied from a tank connected via a tube. By adding the gas tube and tank to the cable from the ratemeter-scaler, the proportional detector is the least convenient to use of those considered here. **Fig. 10** illustrates an example hand-held gas proportional detector (A) and a technician using this detector to scan an object (B). So the obvious question is, why would a surveyor choose to use a gas proportional detector when other options are available? There are two reasons. First, gas proportional can be configured to discriminate between alpha, beta, and alpha-plus-beta radiation. Discrimination is accomplished by varying the Mylar[®] thickness and voltage, like so:

- Alpha-only response by using thinner Mylar[®] and a lower voltage setting.
 - o The Mylar[®] is thin enough for both alpha and beta particles to pass through (mass thickness of 0.4 or 0.8 mg per square centimeter [mg cm⁻²]), and
 - o The voltage is high enough to produce pulses from alpha radiation but is too low to generate a pulse from beta radiation (1100–1400 V).
- Alpha-plus-beta response by using thinner Mylar[®] and a higher voltage setting.
 - o The Mylar[®] is thin enough for both alpha and beta particles to pass through (0.4 or 0.8 mg cm⁻²), and the voltage is high enough to generate a pulse from both alpha and beta radiation (1600–1800 V).
- Beta-only response by using thicker Mylar[®] and a higher voltage setting.
 - o The Mylar[®] is too thick for alpha to pass through but still thin enough to let beta particles to pass through (3.2 mg cm⁻²), and
 - o The voltage is high enough to generate a pulse from beta radiation (1600–1800 V).

These detectors can be used with a dual channel ratemeter to distinguish between alpha and beta response. If paired with a single channel ratemeter, multiple instruments will have to be configured if results for different radiation types are required. For example, one detector can be set for alpha-only, and another for alpha-plus-beta or beta only.

But still, why would a surveyor go through the hassle of the gas tank and tubes, and multiple detectors for different radiation types? The answer is the second reason for selecting gas proportional over other options. As shown in **Table 1**, the gas proportional detector rates "best" for sensitivity to both alpha and beta radiation. This means that in cases where it is important to find low levels of contamination, surveyors may opt for, or even be required to use, gas proportional detectors. The largest probe area or 126 cm² (of those considered) also means the gas proportional is well suited for large area surveys. Speaking of large area detectors, gas proportional detectors also come in large-area varieties (e.g., 500 to over 800 cm²) which are commonly mounted on carts.

The gas proportional detector's high sensitivity to alpha and beta radiation, large probe area, and cart mobility make these detectors ideal for scanning large flat areas, like floors. Because a cart is used, the extra gas tubing and tank is less burdensome. Even when the relatively high sensitivity of a gas proportional is not required, surveyors may want the floor monitor to more easily cover large surfaces in a relatively short time. If elevated radiation levels are discovered using the floor monitor, a surveyor can always use one of the hand-held detectors to hone in on the specific "hot spot" location.

Specialized survey equipment

Specific scenarios may arise throughout a decommissioning process where the instrumentation discussed thus far is either inconvenient or inappropriate to address the problem. This section will outline some instrumentation and equipment used to address

specialized decommissioning problems. Most of the instrumentation presented in this section is commercially available; however, some problems will require novel instrument designs to be manufactured in-house.

Non-destructive assay

Non-destructive assay (NDA) refers to the assessment of a material's radiological properties without the use of destructive means and *ex situ* analysis at a laboratory. Collecting volumetric concrete cores and analyzing the samples at an analytical laboratory is an example of destructive assay. Here passive NDA techniques using gamma ray spectrometry common to decommissioning are outlined. Note that some of the instrumentation previously presented in Section "Common structure/surface survey instrumentation" may fall into the NDA category, however, for the purpose of this chapter, NDA refers to measurements that are intended to quantify radionuclides *in situ*.

High resolution In Situ gamma spectrometry

A lack of information related to the radionuclide source term is a problem for many radiological investigations or material evaluations such as site or waste characterizations. As such, for NDA measurements it is desirable for the detector to resolve neighboring gamma energies associated with different radionuclides. A high purity germanium (HPGe) detector is highly desirable for these applications. Fig. 12 illustrates the use of an HPGe detector for quantifying the radionuclide concentration in structural concrete. The detector setup in Fig. 11 is relatively unremarkable, other than the form of the cryostat and dewar, the components are similar to those used in an analytical laboratory. The key difference is how the efficiency calibration of the detector is performed. Clearly, it

Fig. 11 *In situ* gamma spectrometry measurement of a wall using a portable HPGe detector.

would be difficult to fabricate a standard that represents the measurement geometry presented in Fig. 12. A solution is to use computer software to simulate the detector efficiency under a variety of measurement geometries. From the computer estimated energy efficiency curve and the acquired measurement spectrum, a quantitative value, in terms of activity units, is determined. Often regulators view this equipment as a “black-box” technology. Therefore, it is incumbent on the user to demonstrate that the detector system is accurately assessing the estimated parameter. Quality assurance/quality control (QA/QC) programs typically involve performance testing and confirmatory measurements. For example, a confirmatory measurement may include collecting volumetric samples representative of the detector field-of-view. Volumetric samples may be required anyway to assess hard-to-detect radionuclides that are not detected by gamma spectrometry.

The HPGe detector system mentioned previously can be further specialized for more specific applications, such as automated waste monitoring systems. Commercially available solutions exist for monitoring waste packages or waste shipments. The primary drawback to HPGe detectors is that these detectors are operated at liquid nitrogen temperatures. Detectors can be outfitted with electromechanical coolers that eliminate the need for liquid nitrogen, however these detectors remain sensitive to mechanical shock and must be handled with care.

Hold-up measurements

Consider a decommissioning project that involves dismantling and demolishing a uranium enrichment facility. These facilities house miles of piping that retains a build-up of process material (referred to as product hold-up). When the building is in the normal configuration, this hold-up is in a safe geometry. Now, what happens then we remove the piping and place it in a large pile for disposal. The hold-up went from a distributed state to a fairly condensed pile that may be favorable for a criticality event (unwanted nuclear fission). In order to prevent a criticality event, the quantity of hold-up remaining in the piping must be verified. There are commercially available systems (Fig. 12) that utilize the Generalized Geometry Hold-up methodology, developed at the Los Alamos National Laboratory, to measure the product inside a pipe without dismantling it. The system consists of a specialized detector with either a NaI or LaBr crystal coupled to a portable multi-channel analyzer (MCA) and hand-held software controller to measure 186 keV uranium-235 decay gamma emission and then quantify the weight. As with the previously discussed HPGe-based *in situ* measurement system, performance demonstration and QA/QC programs are important to ensure the measurement system can identify holdup volumes.

Hand-held gamma spectrometers

There are instances where it may be beneficial to simply identify a gamma-emitting radionuclide rather than quantitatively determining its concentration, which greatly simplifies the problem. The detector and associated electronics for this task can be made in a compact form for ease of use in the field. Fig. 13, shows two different isotope identifiers. Crystals used for these applications are lower in resolution than HPGe, such as NaI, cadmium zinc telluride (CZT), and LaBr, which may give rise to limitations depending on the site’s source term and action level objectives. These instruments are fairly easy to use, and operate more along the lines of point-and-shoot, rather than carefully positioning the detector. Gamma energy spectrum acquisition time is on the order of a few minutes, whereas an *in situ* measurement with an HPGe detector may take 15 min or longer. The electronics package typically contains a complex algorithm to analyze the spectrum in order to compensate for the reduced resolution. The unit accesses the

Fig. 12 Example of a measurement system used to quantify uranium-235 hold-up.

Fig. 13 Example of two different hand-held isotope identifiers with LaBr (larger unit) and CsZnTe (smaller unit) detector crystals.

built-in gamma energy library to tentatively identify and then display the radionuclide(s) present. It is helpful for the technician to exercise professional judgment when using this type of instrument.

Pipe detectors

Detectors fabricated for investigating piping generally consist of one or more of the detectors presented in Sections “**Land area (surface soil) survey instrumentation**” and “**Common structure/surface survey instrumentation**”, though packaged in a ruggedized housing. These detectors will collect either qualitative or quantitative measurements, depending on the calibration process. **Fig. 14** shows four different types of pipe monitors, the top two (A and B) are custom made GM based detectors, while the bottom two (C and D) are commercially available scintillation detectors. The type of detector selected for use in the field depends on a number of factors, including the radionuclide of concern and the condition of the pipe. Beta sensitive detectors, such as those in **Fig. 15B** and C, are prone to punctures from debris. A data logger may be coupled to the instrument to electronically record the count rate data. Survey of piping can be extremely challenging due to lack of access or other unknown parameters about the pipe. These detectors are required to be placed inside the piping or ductwork, then physically pulled through, or in some cases can be mounted to a robotic transport vehicle.

Calibration of the detector is an important factor to consider, and it can be challenging to calibrate the detector in a geometry that is representative of field conditions. If hot spots are a concern, then it may be appropriate to calibrate the detector with a small area source, such as button source. However, for typical decommissioning projects involving the survey of piping, the parameter of interest is related to the total residual activity contained within the pipe. Therefore, it may be necessary to calibrate the detector with a large area flexible source. The flexible source is placed inside of a pipe surrogate to simulate the geometry of the field measurements.

Gamma imaging systems

Remediation planning and implementation would be a lot easier if we could visually see the radiation. Human senses cannot detect ionizing radiation, we therefore need to use sophisticated detector systems to audibly or visually represent the radiation. Detectors in this visual classification are often informally referred to as gamma cameras. CZT is a typical detector crystal of choice due to room temperature operation, and better resolution than NaI. The gamma camera is placed in a stationary position in front of the item to be imaged, and a spectrum is acquired. Using complex computer algorithms and the acquired spectrum, the radiation intensity is overlaid on a digital image. **Fig. 15** provides an example of a resulting image. Because the CZT detectors and electronics typically have spectroscopic capability, different heat maps for each radionuclide of interest are generated. Pure beta emitters are not detected by these systems, so one must either know the relationship of the beta emitter to a gamma emitter, or use a different type of detector and measurement method (i.e. scanning with a plastic scintillator).

Fig. 14 Specialized commercial and custom-built detectors for assessing pipe internals: (A) small GM-detector, (B) 3 GM detectors in a ruggedized housing, (C) 5.1×5.1 cm NaI Ball detector, and (D) CsI detector.

Fig. 15 Example gamma camera image of reactor piping (red represents the highest radiation levels).

Position-sensitive structural survey systems

Because building structures block satellite reception of GPS receivers used for outdoor gamma walkover surveys, alternative methods must be employed indoors if one wishes to generate position and radiation level maps similar to Fig. 7. A laser measurement system, similar to that used by highway surveyors, can be repurposed to map indoor radiological surveys. Fig. 16 shows

Fig. 16 Large-area gas proportional floor monitor coupled to position sensitive robotic total station.

a large-area gas proportional detector used to survey floors and with the right type of cart and adapter arms, the detector could be turned vertically to scan walls. The detector in the example includes a prism mounted on a pole. The prism allows for continuous line-of-sight laser tracking using the robotic total station seen mounted on the tripod, and with a data logger, the count rate and position data can be electronically recorded and mapped similar to that described for land area surveys. Fig. 17 shows a 3-D plot of structural scan data collected with such a system.

Additionally, there are automated scanning systems that remove the human aspect of scanning. A detector is attached to a track that is mechanically moved across the building surface. The obvious advantage of these systems is that the motion of the detector and distance to the surface remains constant as surveyor fatigue is eliminated. Disadvantages to these type of systems include a fairly complex setup process and limitations due the physical layout of some structures that interfere with (block) the laser tracking

Fig. 17 3-D rendering of a research reactor bay alpha-plus-beta scan data.

resulting in the need to reposition the base station, which can be timely. Surfaces that are not smooth, because of remediation, may prevent the use of automated systems, unless system can continuously vary the surface to detector distance to account for uneven surfaces.

Laboratory analysis and instrumentation

Portable field detectors and associated hardware play a key role in routine radiological investigations of land areas and structures during decontamination and decommissioning activities. In fact, one may argue that these types of detectors and instruments are the dominant tool used for the detection and, under certain conditions, the quantitative determination, of radioactive material during clean-up activities. Although these detectors provide a large amount of information and data to the user, there are times in which more information and data about the material being scanned is needed. Laboratory analyses may be needed to obtain detailed sample information and data. Laboratory analyses optimize measurement conditions and has several advantages over field measurements. Some of these advantages include identification and quantification of specific radionuclides, individual radionuclides separations, better detection limits, and better quality control.

This section discusses some of the commonly used radiological sample analysis methods and the associated laboratory instrumentation. Sample analyses can be divided into two broad categories: non-destructive analyses and destructive analyses. The types of instrumentation used for sample counting is often used for both types of analyses.

Non-destructive analysis

Non-destructive analyses are types of sample analyses in which the sample is not processed in a way to change its physical or chemical form (other than drying the sample). In addition, the sample is not consumed during analyses. Two common non-destructive analyses in a radiochemistry laboratory include gamma spectrometry and gross alpha and beta (GAB).

Gamma spectrometry

Gamma spectrometry allows for both the identification and quantification of multiple radionuclides simultaneously. A large percentage of radionuclides—such as cesium-137, cobalt-60, and many others—that are often associated with decontamination and decommissioning sites can be analyzed and quantified by gamma spectrometry. In fact, only radionuclides that are pure alpha or pure beta emitters cannot be analyzed by gamma spectrometry.

Gamma rays are electromagnetic radiation produced in the nucleus of an atom. These rays are photons and have energy (50–3000 keV) but no mass or charge, and therefore, do not readily interact or transfer their energy in matter. When a gamma photon does interact and deposit energy, the interaction is via one of three principle means: the photoelectric effect, Compton scattering, or pair production. All three types of interactions occur when a gamma photon interacts with the detector material. However, it is the photoelectric effect interaction that creates the well resolved energy peak from the radionuclide.

Most current laboratory gamma spectrometry systems use solid-state semi-conductor detectors, namely HPGe, coupled with a high voltage power supply, pre-amplifier, amplifier, MCA, analogue to digital converter (ADC), shield, dewar with liquid nitrogen (the HPGe must be kept at liquid nitrogen temperatures), and computer software to deconvolute the spectra. Fig. 18 depicts a dewar and shield and Fig. 19 shows the inside of the shield with an HPGe detector.

Nearly any type of matrix may be analyzed by gamma spectrometry as long as there is an available calibration source (both for energy and efficiency) and counting geometry. Sample types include soil, water (ground, surface, drinking), air filters, smears, vegetation, construction materials, wastes, etc. Sample preparation for gamma counting is usually minimal and requires only homogenization of the sample and putting the sample in a calibrated counting container (geometry). However, for more difficult matrices like construction material, the sample may need to be acid-leached prior to counting. HPGe detectors have extremely good energy resolution (~ 1 – 2 keV) and are typically used for gamma emissions between 50 and 2000 keV (although there are detectors that can be used below 50 keV). Fig. 20 shows a spectrum of a soil sample with the 186 keV peak for Ra-226 in orange (spectrum is shown with a linear scale).

Advantages and disadvantages of gamma spectrometry are shown in Table 2 below.

Gross alpha and gross beta for smear samples

There are some circumstances in which the total beta activity or total alpha activity (or both) of a sample needs to be determined. This total activity is called the “gross” activity of either alpha or beta activities. Gross alpha and beta (GAB) measurements are often used as a screening tool to determine.

GAB analyses are often performed on smear samples at D&D sites to determine if removable activity is present on solid surfaces (walls, floors, equipment, etc.) and if the removable activities are above some defined personnel protective or other limit. The smears collected in the field are sent to the laboratory, up to 100 smears loaded onto the instrument, and counted sequentially. The count times are usually short, thus, results can be provided to the project manager within a few hours.

Other sample types may be counted for GAB, including soil, air filters, and water. Usually these analyses are done to screen a sample for radioactivity and determine when radionuclide-specific analyses are necessary. Fig. 21 depicts two low-background

Fig. 18 Lead shield and dewar with liquid nitrogen.

Fig. 19 Inside lead shield with HPGe detector.

proportional counters used for GAB analysis. Note the long, extended sample holders which can hold up to 100 smears for sequential counting.

Advantages and disadvantages of GAB smear analyses are shown in [Table 3](#) below.

Destructive analysis

Destructive analyses are types of sample analyses in which the sample is processed in a way to change its physical or chemical form. In addition, the sample, or a portion of the sample is typically consumed during analyses. Often, the sample undergoes some type of

Fig. 20 Gamma spectrum showing the Ra-226 peak in orange.

Table 2 Advantages and disadvantages of gamma spectrometry using HPGe.

<i>Advantages</i>	<i>Disadvantages</i>
Non-destructive (typically)	Cannot analyze pure alpha or beta emitters (e.g. Pu-239, U-234, Sr-90, etc.)
Multi-isotope	Requires very good calibrations
Relatively fast analysis	Requires large and heavy shields
Several counting geometries (if calibrated)	Requires liquid nitrogen or mechanical chillers
Excellent energy resolution	Isotopes with similar energy must be interpreted by experienced workers
Good detection limits (with adequate count time)	
Many matrix types	
Excellent software available for data reduction	
Tolerates high radioactivity	
Good tool for sample radionuclide screening without quantification	
Relatively inexpensive analysis cost	

chemical separation to purify the radionuclide(s) of interest prior to sample counting. This section will provide a brief discussion on sample preparation for various sample matrices, along with the most common sample analyses performed after sample preparation—alpha spectrometry, liquid scintillation, and low-background proportional counting.

Sample preparation

Sample preparation is often the most overlooked and underappreciated aspect of sample analysis. The final analytical data generated from the sample analysis is only as good as the sample preparation prior to the analysis. Two major goals of sample preparation are to provide representative aliquots that are free from laboratory contamination and to avoid sample loss that will be used in the next steps of the laboratory protocol. It is also of utmost importance to understand the data quality objective for the project prior to commencing sample preparation as some preparation methods may not be suitable for the requested analyte.

For solid samples including soil, sediment, biota, animal tissue, filters, metal, concrete, etc.), the sample is typically dried to a constant mass at a low temperature. This is done because most radiological results for solid materials are reported on a dry weight basis (although some solid materials such as food-stuffs are often reported on an “as received” basis, or wet basis). After drying, the samples may also be dry ashed to remove unwanted organic material. Next, the samples are homogenized via grinding, blending, or other mechanical method. Matrices that cannot be homogenized—e.g. metal, asphalt, etc.—are often acid-leached to remove any radionuclides from the surface. The percentage of the activity removed is estimated by making a pre- and post-leaching measurement on the sample surface using a hand-held detector or by gamma spectrometry. The acid leach is then brought up to a known volume for use in the final concentration calculation.

Once homogenization and processing are complete, sub-samples (aliquots) are taken and subjected to the various requested specific analyses. The aliquots for destructive analyses are usually digested by some means—either complete dissolution or acid-leaching. Complete dissolution may be accomplished by a variety of fusion-type reactions at high temperature. The fusion ensures the analyte is taken into an aqueous media and allows the chemist to manipulate the element for the subsequent chemical separations.

Fig. 21 Low background proportional counters.

Table 3 Advantages and disadvantages of GAB for smears analysis.

<i>Advantages</i>	<i>Disadvantages</i>
Non-destructive (typically)	No isotopic speciation
Good screening tool	Fair to poor detection limits
Fast analysis	High uncertainties
Inexpensive	

Aqueous samples are often filtered and acidified prior to sample analysis. Again, one must know the data objectives prior to performing either. Acidification is performed to reduce the chance the analyte will absorb to the container walls. This is particularly a concern for the larger analytes such as plutonium and uranium.

Table 4 lists common sample preparation techniques for various matrices and **Fig. 22** shows a soil sample undergoing high-temperature fusion.

The following are important factors to consider as part of sample preparation:

- **Potential Sample Losses During Sample Preparation**

There are three main ways in which a portion of the sample or analyte may be lost during sample preparation. Loss mechanisms can be monitored and the sample results adjusted accordingly by the addition of carriers or tracers at the earliest point during the sample preparation. These added tracers and carriers allow one to calculate the amount of analyte loss.

First, drying samples in an oven or dry-ashing in a muffle furnace will often make the sample produce fine particulates or dust. These particles can easily be lost from air currents from temperature changes or from chemical hoods. Second, some radio-nuclides are volatile under certain conditions and care must be taken during preparation and analyses, such as drying samples

Table 4 Sample preparation by sample matrix.

<i>Sample type</i>	<i>Sample preparation</i>
Soil/sediment	Dry Homogenize Subsample Fusion Acid leach Microwave digestion
Vegetation	Dry (% moisture) Homogenize Subsample Fusion Acid leach Microwave digestion
Biota	Dry (% moisture) Homogenize Subsample Fusion Acid leach Microwave digestion
Air Filters	Fusion Acid leach Microwave digestion
Concrete/asphalt, construction materials	Acid leach
Water (ground, surface)	Acidify Filter

**Fig. 22** Fusion of soil sample.

below the analyte's boiling. In addition, reagents may be added to the sample to change the chemical form of the analyte to a less volatile form. Last, some elements may react and adsorb into the sample container or preparation container. Acidification of the glassware or liquid samples is sometimes required to prevent adsorption.

- Contamination Control

Because of the emphasis on sample data for decision making, cross contamination between samples must be avoided. That begins in the field when the sample is first collected. Clean sample implements are used to collect each sample, samples are individually containerized, and prevented from leaking. Once in the laboratory, sources of contamination could include the certified pure chemical reagents are used, glassware and equipment must be kept clean, and the potential for airborne contamination or transfer between samples eliminated. Simple techniques include working within hoods, covering samples, using disposable or thoroughly cleaning labware, and sample segregation. Laboratory blank analyses using all the reagents used for the samples can provide information regarding any cross contamination that may occur from the reagents or labware.

Alpha spectrometry

Several types of detectors, such as ionization chambers, proportional counters, solid-state silicon semiconductors, and scintillators (ZnS, plastic, liquid), can measure alpha particles. The most common type of detection system in a laboratory is the solid-state silicon semiconductors that have a high-voltage power supply, preamplifier, amplifier, pulse discriminator, scaler, and recording device. An ADC and MCA is also required for spectrometry systems. Since alpha particles do not travel far distances, even in air, the alpha detector and sample is placed under vacuum.

Alpha spectrometry is an excellent way to identify and quantify alpha-emitting nuclides. Common D&D encountered radionuclides such as americium-241, plutonium-238, plutonium-239/240, thorium-228, thorium-230, thorium-232, uranium-233/234, uranium-235/236, and uranium-238 as well as any radionuclide that emits alpha radiation may be detected on the system. Nearly any sample type may be analyzed by alpha spectrometry. The detection limits and spectral resolution are very good. However, the chemical separations needed for ideal counting conditions is time-consuming and requires experienced chemists. **Table 5** lists the advantages and disadvantages of alpha spectrometry. **Fig. 23** depicts a solid-state semiconductor alpha spectrometer system and **Fig. 24** shows a natural uranium spectrum from a soil sample.

Liquid scintillation counting

Liquid scintillation counting (LSC) is often the method of choice for measuring radionuclides that decay by low energy beta emission or for radionuclides that are pure beta emitters, i.e. no associated gamma ray. However, LSC is versatile enough that it can be used for higher energy beta and alpha emitters. LSC is an analytical option for all types of sample matrices including water (tritium), smears, and soils. Samples can be prepared with or without chemical separation and placed into a liquid scintillation “cocktail”.

Table 5 Advantages and disadvantages of alpha spectrometry.

<i>Advantages</i>	<i>Disadvantages</i>
Excellent resolution	Time consuming
Good stability (low energy drift)	Requires well trained staff
High efficiency	Requires good analyte separation
Good detection limits	Potential interferences if separation is not complete
Good uncertainties	

Fig. 23 Solid-state alpha spectrometry system.

Fig. 24 Natural uranium spectrum in soil sample.

When the radioactive particle transfers its energy to the fluor in the cocktail, photons of light are produced. The amount of light produced is proportional to the activity in the sample.

LSC has very high measurement efficiencies because the sample is completely surrounded by the detection molecules of the cocktail. In fact, beta energies greater than 200 keV have essentially a 100% counting efficiency. However, this high efficiency is countered by the loss of resolution because beta emissions follow an energy continuum, two or more beta emitting radionuclides in a mixture generally cannot be distinguished without chemical separation. Therefore, LSC is often a screening method to quantify the “total activity” of a sample by examining the full 0–2000 keV energy range (this would include alpha and beta activity).

A picture of a typical liquid scintillation counter is depicted in [Fig. 25](#). Advantages and disadvantages of liquid scintillation counting are shown in [Table 6](#).

Low background proportional counting

As mentioned previously, low background proportional counting (LBPC) is a common method to count smears for gross alpha and beta activities. However, this method is also commonly used to measure the activities in medium to high energy beta emitters after

Fig. 25 Liquid scintillation counter.

Table 6 Advantages and disadvantages of liquid scintillation counting.

<i>Advantages</i>	<i>Disadvantages</i>
Excellent for low energy beta emitters	Cannot distinguish radionuclides in a mixture
Good for smear samples	Requires chemical separation for radionuclide-specific determination and quantification
Excellent efficiency	Potential interferences if separation is not complete
Low uncertainties and detection limits.	

Table 7 Advantages and disadvantages of low background proportional counting.

<i>Advantages</i>	<i>Disadvantages</i>
Good efficiencies for alpha and beta of medium to high energies	Time consuming
Good stability (low energy drift)	Requires well trained staff
Can count alpha and beta simultaneously	Requires chemical separation for radionuclide-specific determination and quantification
Low detection limits and uncertainties	Potential interferences if separation is not complete
Relatively simply instrumentation	

Table 8 Advantages and disadvantages of low background proportional counting.

<i>Advantages</i>	<i>Disadvantages</i>
Extremely sensitive	Relatively complex instrument
Good stability (low energy drift)	Requires well trained staff
Multiple analytes simultaneously	Requires good separation of analytes
Very low detection limits (parts per billion) and uncertainties	Potential interferences of isobars (e.g. U-232/Th-232)
Excellent	Potential matrix interferences
Relatively fast analysis after sample prep	

chemical separations. LBPC are typically calibrated such that alpha can be distinguished from beta radiation by controlling the applied voltage to the detector. The counting efficiency is good for both alpha and beta emission, but not as high as liquid scintillation. As with liquid scintillation, LBPC cannot distinguish energy differences between beta particles or between alpha particles. Thus, other than for GAB analysis, separation chemistry is required to isolate a single radionuclide prior to counting. Advantages and disadvantages of LBPC are listed in [Table 7](#).

Inductively coupled plasma mass spectrometry

Inductively Coupled Plasma Mass Spectrometry (ICPMS) is another destructive method used for the determination of long-lived radionuclides (those with half-lives > 10,000 years). Nearly any sample type after proper processing may be analyzed by ICPMS. Processed samples are introduced into the instrument and the sample is de-solvated, atomized and ionized in the plasma. The resulting ions are then separated by the mass spectrometer based on their mass to charge ratio. Thus, ICPMS does not measure the samples radioactivity, but it measures the mass of the sample. ICPMS is often used for the measurement of isotopic uranium, plutonium-239/240, and technetium-99. The method offers several advantages including very high sensitivities (low detection limits), multiple radionuclides can be measured nearly simultaneously, fast analysis once the sample is prepared, and can resolve elemental isotopes that alpha spectroscopy cannot distinguish (plutonium-239/240). However, the instrument cost is relatively high and requires a well-trained personnel to operate.

Advantages and disadvantages of ICPMS are listed in [Table 8](#) below.

Introduction

Radiation protection in emergency response is challenging. In “normal” working conditions sources are well understood and doses are able to be kept well below regulatory limits. Conversely, in emergency response you may not immediately know your source term, amount or even the type of radiation involved. Additionally, there may be situations where responders or even the public may receive a recordable dose far higher than is normally permitted in an occupational setting. The goal in emergency response health physics is to make sure that immediate doses due to the situation will not result in non-stochastic effects (radiation sickness) and that any doses received will minimize the risk of long-term stochastic effects (cancer). These goals are applied to responders and public alike. The purpose of this chapter is to introduce emergency response radiation protection and how it is applied during a radiological event.

Protective actions

In order to minimize radiation doses during an event it is imperative that protective actions be taken. For the public, these actions would be established and implemented by the local, state or the federal government. Protective actions could include shelter-in-place, evacuation, administration of prophylactic drugs, relocation and food supply warnings/interdictions. All of these can cause major disruptions in the daily routines of the public and each must be carefully considered before implementation.

To help public officials during a radiological event the Environmental Protection Agency (EPA) created a document that provides protection action guides (PAGs) that are used to determine when protective actions are warranted. The *PAG Manual: Protective Action Guides and Planning Guidance for Radiological Incidents* was revised in 2017 and is sometimes simply called EPA400 (EPA, 2017). This document defines a PAG as “the projected dose to an individual from a release of radioactive material at which a specific protective action to reduce or avoid that dose is recommended.” In a radiological emergency, experts would take radiological data from the field to estimate future doses. Advisors to a public official (or decision maker) would then relate how these doses relate to PAGs. Based on the provided information and advice it is the decision maker that determines if (and what) protection actions should be implemented.

PAGs are not legally binding regulations and do not need to be strictly followed because other risks may exist. The key word in PAG is “guide,” because these values should only be considered when taking into account the unique environment of the radiological event and the risks involved when the PAG is executed. Implementing a PAG only reduces the health risk caused by the radiation, but there are other risks to be considered. For instance, during a radiological release it is projected that a large area may need to be evacuated. If everyone in the affected area simultaneously tries to evacuate, what are the risks of fatal accidents with so many cars suddenly on the road? If traffic jams are caused, is the public then being exposed to more radiation because they are stuck outdoors in the plume? Similarly, if a blanket order is given to evacuate what do you do for sensitive populations? Is the risk of death to hospitalized patients in critical condition greater because they are being moved or from the dose they may receive? Implementing a PAG is a complex judgment process because sometimes the radiation might not be the most critical factor to consider.

Phases of an emergency and how they relate to PAGs

Radiation protection considerations during an emergency are broken down into phases to aid in response planning. The beginning of the radiological incident is defined as the *Early Phase* and can last for hours to days. It is during this period that immediate decisions on protective actions could greatly reduce the doses due to inhalation or plume passage. Protective actions during the Early Phase would be based on predictions of radiological conditions or available measurements. They could even be based on the

Table 1 Emergency phases and their associated PAGs (EPA, 2017).

Phase	Protective action recommendation	PAG, Guideline, or planning guidance
Early Phase	Sheltering-in-place or evacuation of the public Supplementary administration of prophylactic drugs	PAG: 1 to 5 rem (10 to 50 mSv) projected dose over 4 days PAG: 5 rem (50 mSv) projected child thyroid dose from radioactive iodine
Intermediate Phase	Relocation of the public	PAG: ≥ 2 rem (20 mSv) projected dose in the first year; 0.5 rem (5 mSv) per year projected dose in the second or subsequent years
	Apply simple dose reduction techniques Food interdiction	Guideline: < 2 rem (20 mSv) projected dose in the first year PAG: 0.5 rem (5 mSv) per year projected whole body dose, or 5 rem (50 mSv) per year to any individual organ or tissue, whichever is limiting
	Drinking water	PAG: 0.1 rem (1 mSv) projected dose for 1 year, to the most sensitive populations (e.g. infants, children, pregnant women and nursing women); 0.5 rem (5 mSv) projected dose, for 1 year, to the general population
	Reentry	Guideline: Operational Guidelines (stay times and concentrations) for specific activities

potential of worsening conditions. In most cases the protective action during the Early Phase is evacuation or shelter-in-place and is triggered if the projected dose could reach 1–5 rem (10–50 mSv) over 4 days of exposure (Table 1). Sometimes default protective actions are established before an accident even happens to assure the public is protected as rapidly as possible. For instance, in some states for a nuclear power plant accident, evacuation and shelter-in-place orders would be initiated 360° within a 10-mile radius of the plant. If there is a potential of a radiological release due to facility conditions or other events, protective actions can be initiated before the event occurs.

The *Intermediate Phase* begins when the initiating event has been brought under control. Unlike the Early Phase, protective action decisions will primarily be based on environmental measurements that define the radiological environment. Actions taken during this phase could include population relocation, food embargos and implementing water restrictions. The different PAGs associated with this phase, listed in Table 1, are meant to protect that portion of the public who was not immediately affected by the release, but may receive an accumulated dose from deposited material. This phase could last from weeks to months and may overlap with the Early Phase.

The US Food and Drug Administration (FDA) has issued guidance based potential doses received from the ingestion of food (FDA, 1998). These are typically implemented during the Intermediate Phase. The FDA suggests *Intervention Levels* that are based on PAGs of 0.5 rem (5 mSv) Committed Effective Dose or 5 rem (50 mSv) to any specific organ. These Derived Intervention Levels (DILs) are established for 24 radionuclides and represent the concentration ($\mu\text{Ci kg}^{-1}$) of radioactive material in food that, in the absence of any intervention, will lead to an individual reaching a PAG (Table 2). These DILs are for food ingested during the first year after an accident and are based on the most sensitive population (usually an infant less than 3 months old) and target organ. This conservatism is meant to provide a large margin of safety to the exposed public. DILs for other radionuclides can be calculated and the resources to do so are listed later in this chapter.

The Late Phase focuses on clean-up and attempting to bring environmental doses back to pre-event levels. This phase can last months to years and ends only when all recovery actions have been completed. Since this phase focuses on long term clean-up, dose avoidance through the use of PAGs is not appropriate. Since this phase occurs after the actual emergency, it will not be discussed in this chapter.

Dose guidelines for emergency responders

EPA400 also provides guidance for emergency response personnel. In a radiological incident responders could be exposed to elevated levels of radioactivity. In most cases, when following proper precautions doses can be kept below the annual occupational dose limit of 5 rem (50 mSv). It can still take several hours or days to reach this limit even working in what would be considered a high radiation field in “normal” conditions. A responder may find themselves working in 100 mrem hr^{-1} (1 mSv hr^{-1}) field to save trapped victims. In a normal occupational setting this radiation field would be unacceptable, but in an emergency, it could be unavoidable. Even in this elevated dose rate area a single worker would have to continuously work 50 h to even reach the “normal” limit. There may be situations like responding to an improvised nuclear device (IND) or serve reactor accident, where radiation fields are extremely high, but operations must take place to save lives or make sure the situation does not worsen. Any dose received during a radiological emergency should still follow ALARA (As Low As Reasonably Achievable) concepts: the risk of the accumulated dose is justified by the benefit of the actions.

Table 2 List of DILs for the 24 specific nuclides established by the FDA (DOE, 2010).

Radionuclide Group	FDA DIL ^a (Bq/kg _{wet})	FDA DIL ^a (μCi/kg _{wet})
<i>Principal Nuclides</i>		
⁹⁰ Sr	160	4.3E-03
¹³¹ I	170	4.6E-03
¹³⁴ Cs + ¹³⁷ Cs	1200	3.2E-02
¹³⁴ Cs	930	2.5E-02
¹³⁷ Cs	1360	3.7E-02
²³⁸ Pu + ²³⁹ Pu + ²⁴¹ Am	2	5.4E-05
²³⁸ Pu	2.5	6.8E-05
²³⁹ Pu	2.2	5.9E-05
²⁴¹ Am	2	5.4E-05
¹⁰³ Ru + ¹⁰⁶ Ru	(¹⁰³ Ru/6800) + (¹⁰⁶ Ru/450) < 1	(¹⁰³ Ru/0.18) + (¹⁰⁶ Ru/1.2E-02) < 1
¹⁰³ Ru	6800	0.18
¹⁰⁶ Ru	450	1.2E-02
<i>Other Nuclides</i>		
⁸⁹ Sr	1400	3.8E-02
⁹¹ Y	1200	3.2E-02
⁹⁵ Zr	4000	0.11
⁹⁵ Nb	12,000	0.32
¹³² Te	4400	0.12
¹²⁹ I	56	1.5E-03
¹³³ I	7000	0.19
¹⁴⁰ Ba	6900	0.19
¹⁴¹ Ce	7200	0.19
¹⁴⁴ Ce	500	1.4E-02
²³⁷ Np	4	1.1E-04
²³⁹ Np	28,000	0.76
²⁴¹ Pu	120	3.2E-03
²⁴² Cm	19	5.1E-04
²⁴⁴ Cm	2	5.4E-05

^aA food sample is considered to exceed the DIL if it meets or exceeds the DIL for any individual nuclide. Analysis results are not summed across nuclides except the combinations specifically stated (i.e., ¹³⁴Cs + ¹³⁷Cs, ²³⁸Pu + ²³⁹Pu + ²⁴¹Am, and ¹⁰³Ru + ¹⁰⁶Ru).

Table 3 lists the suggested guidelines from EPA400. Like the public PAGs, these are only guides and not set limits. The National Council on Radiation Protection even suggests the concept of a “decision dose” at 50 rem (500 mSv) (NCRP, 2010). It is at this dose that an incident commander should decide to remove a responder from the field or let them remain to accomplish mission critical actions. All of the values listed in **Table 3**, and the decision dose, are below dose levels where radiation sickness occurs (**Table 4**) and at levels where the risk of the onset of cancer in later years is minimized. To make sure all responders know how to reduce their doses during operations they should be properly trained. At a minimum this training should include elements of the emergency response plan, operating procedures and procedures for notification and handling of emergency nuclear and radiological incidents (NCRP, 2005).

Table 3 Dose guidelines for emergency responders (EPA, 2017).

Guideline	Activity	Condition
5 rem (50 mSv)	All occupational exposures	All reasonably achievable actions have been taken to minimize dose
10 rem (100 mSv)	Protecting critical infrastructure necessary for public welfare (e.g. a power plant)	Exceeding 5 rem (50 mSv) in unavoidable and all appropriate actions have been taken to reduce dose Monitoring available to project or measure dose
25 rem (250 mSv) ^a	Lifesaving or protection of large populations	Exceeding 5 rem (50 mSv) in unavoidable and all appropriate actions have been taken to reduce dose Monitoring available to project or measure dose
> 25 rem (250 mSv)	Lifesaving or protection of large populations	Exceeding 5 rem (50 mSv) in unavoidable and all appropriate actions have been taken to reduce dose Monitoring available to project or measure dose

^aIn the case of a very large incident, such as an IND, incident commanders may need to consider raising the property and lifesaving emergency worker guidelines to prevent further loss of life and massive spread if destruction.

Table 4 Radiation levels where acute radiation sickness are witnessed (EPA, 2017).^a

Feature or Illness	Effects of whole body absorbed dose from external radiation or internal absorption, by dose range in rad (gray)				
	0–100 (0–1 Gy)	100–200 (1–2 Gy)	200–600 (2–6 Gy)	600–800 (6–8 Gy)	> 800 (> 8 Gy)
Nausea, Vomiting	None ^b	5–50%	50–100%	75–100%	90–100%
Time of Onset		3–6 h	2–4 h	1–2 h	< 1 h to minutes
Duration		< 24 h	< 24 h	< 48 h	< 48 h
Lymphocyte Count	Unaffected	Minimally Decreased	< 1000 at 24 h	< 500 at 24 h	Decreases within hours
Central Nervous System Function	No Impairment	No Impairment	Cognitive impairment for 6–20 h	Cognitive impairment for > 20 h	Rapid incapacitation
Mortality	None	Minimal	Low with aggressive therapy ^c	High	Very High: Significant neurological symptoms indicate lethal dose

^aPercentage of people receiving whole body doses within a few hours expected to experience acute health effects.

^bA small number of exposed individuals may experience symptoms such as nausea and vomiting at dose between 50 and 100 rad (0.5 and 1 Gy).

^cThe lethal dose with NO medical intervention to 50 percent of the population in 60 days is between 320 and 450 rad or 3.2–4.5 Gy.

From DoD (2003) *Medical Management of Radiological Casualties*, 2nd edn. Bethesda, MD: Armed Forces Radiobiology Research Institute. April 2003.

Tracking doses to first responders has been made easier with technology. Now many first responders carry alarming personal radiation dosimeters. These devices monitor both dose rate and accumulated dose. If preset levels are exceeded, the device would alarm warning the individual of the current radiation levels. These types of instruments only register gamma radiation because it is assumed that normal personal protective equipment (bunker gear, gloves, respirator, etc.) would protect the responder from other forms of radiation like alpha and beta particles. The UltraRadiac™-Plus is an example of such a device manufactured by Mirion Technologies. It is a rugged alarming radiation monitor specifically designed for first responders. It has a detection range between $1 \mu\text{rem hr}^{-1}$ and 200 rem hr^{-1} ($0.01 \mu\text{Sv hr}^{-1}$ – 2 Sv hr^{-1}) and an accumulated dose range of $0.1 \mu\text{rem}$ – 999 rem ($0.001 \mu\text{Sv}$ – 999 Sv) (Mirion Technologies, 2018). Devices such as these will warn responders well before any set limits for an event are surpassed.

Risk related to dose

Dose guidelines are based on the relative risk of the radiation dose. Risk levels have been established based on several studies including clinical studies, research on atomic bomb survivors and severe accidents involving radioactive material. Table 5 lists radiation effect risks as a function of absorbed dose. These risks are compared to the lifetime risk of fatal cancer without radiation exposure. Even without being exposed to radiation the lifetime risk of an individual dying from cancer is 24% (24 cases out of 100 people). Notice that even at the decision dose of 50 rem that the excess risk only increases by 4%. At the 10 rem guide (protection of property) the risk is less than 1%. In comparison, smoking can increase the risk of prostate cancer by 9–30% and risk of lung cancer by 15–30 times. The point is that while emergency dose guidelines may seem high compared to normal operations, the relative risk to the exposed individuals are still low.

There may be an age consideration when assigning duties to emergency responders. One point of limiting doses is to reduce the risk of cancer. Due to the latency period of cancer, younger responders face a larger risk of fatal cancer than their older counterparts.

Table 5 Values for the acute death, acute symptoms, and fatal cancer risk as a function of whole body dose equivalent. These values are compared to the lifetime risk of fatal cancer without radiation exposure (NCRP, 2005).

Short-term whole-body dose [rem (Sv)]	Acute death from radiation without medical treatment (%)	Acute death from radiation with medical treatment (%)	Acute symptoms (nausea and vomiting within 4 h) (%)	Lifetime risk of fatal cancer without radiation exposure (%)	Excess lifetime risk of fatal cancer due to short-term radiation exposure (%)
1 (0.01)	0	0	0	24	0.08
10 (0.1)	0	0	0	24	0.8
50 (0.5)	0	0	0	24	4
100 (1)	<5	0	5–30	24	8
150 (1.5)	<5	<5	40	24	12
200 (2)	5	<5	60	24	16
300 (3)	30–50	15–30	75	24	24
600 (6)	95–100	50	100	24	>40
1000 (10)	100	>90	100	24	>50

For individuals between 20 and 30 years old, they have a 0.9% risk of premature death when exposed to 25 rem (250 mSv), while 40–50 years olds have a 0.5% risk of premature death.¹ Therefore, using older responders in higher radiation fields could be justified based on the increased risk of the younger responders.

Estimating dose

Estimating the potential dose to the public and responders can be a complicated process. During a response these calculations are made using techniques described in the Federal Radiological Monitoring and Assessment Center (FRMAC) Assessment Manual (DOE, 2018). This three volume, multi-agency document was created from the input of 9 Federal agencies, reviewed by experts across the health physics community and forms the basis of how United States' response teams would calculate doses during an emergency. It utilizes the International Commission on Radiological Protection (ICRP) 60 methodology to estimate doses from 44 different radionuclides that would be common across different radiological emergencies. It also provides techniques for experts to determine doses from other nuclides not listed in the document. It is separated into four different sections:

- Public Protection
- Emergency Worker Protection
- Ingestion Pathway Analysis
- Supplemental Methods

To anticipate the dose assessment needs that would occur for different radiological emergency events, Volume 2 of the Assessment Manual contains default scenarios. This volume is meant to expedite response for specific events before field data becomes available and uses "expected" nuclides and dispersion methods. These pre-assessed events include:

- Nuclear power plant accident
- Nuclear weapon accident
- Aged fission product accident
- Nuclear fuel accident
- Radionuclide thermoelectric generator (RTG) accident
- Radiological dispersal device (RDD)
- A domestic nuclear explosion is under development

Each default scenario includes an event description, possible radionuclides, potential consequences, potential actions, required measurements for prediction tools and default dose rate and dose values known as Derived Response Levels (DRLs) that help predict areas where PAGs should be implemented.

In addition to the Assessment Manual, dose assessment professionals can use software to estimate exposure to the public and responders. In fact, the dose Assessment Manual serves as the scientific basis for the software package called TURBO-FRMAC®. Used by trained health physicist this software automates the calculations performed in the manual. It can rapidly calculate DRLs and estimate doses based on field data collected by response teams. While it does initially use default values based on generic scenarios, assessment scientists can modify inputs to accommodate incident-specific conditions.

How a response progresses

A radiological incident can take many forms. It can be as simple as a vehicle accident involving only local responders and a small localized spill to an IND affecting thousands of square miles. In many cases local responders can handle the situation, but there are cases where local responders and officials will be overwhelmed and need assistance from state and federal authorities. At each stage, the response can end and not require the full assistance of the federal government. It should be noted that no matter the size of the incident there are support mechanism within the federal government that will come to the aid of local and tribal authorities to assist in the response. This aid can take the form of advice over the phone to sending experts to the affected area. Below is a description of how a response can progress. It will include several teams that could respond and their functions.

The timeline described below is primarily from the perspective of the Department of Energy's (DOE) National Nuclear Security Administration (NNSA). Under the National Response Framework (NRF) Nuclear/Radiological Incident Annex (NRIA) the DOE is given the responsibility to coordinate federal radiological monitoring and assessment activities during many radiological emergencies (DHS, 2016). Other response functions and teams will most likely respond as well. Response teams can also vary based on the type of incident. If it is a deliberate event the Federal Bureau of Investigation (FBI) would coordinate the response and utilize some

¹The numerical estimate of cancer risk presented above (from Federal Guidance Report #13) was obtained by linear extrapolation using the nominal risk estimates based on data from human exposures at high doses and high dose rates. Other methods of extrapolation to the low-dose region could yield higher or lower numerical estimates of cancer deaths. Studies of human populations exposed at low doses are inadequate to demonstrate the actual magnitude of risk at low doses (about 0.1 Sv or 10 rem and below). There is scientific uncertainty about cancer risk in the low-dose region below the range of epidemiological observation and the possibility of no risk cannot be excluded (EPA, 1999).

of its response assets. If it is an accident, other federal agencies may coordinate the response. However, it is still the DOE that would organize the radiological assessment.

Below is a generic timeline of a major radiological emergency (Fig. 1). It is only meant to show what assets will arrive to support the situation in a general time period. Depending on the location of the event, response teams may be closer and arrive much faster. In many cases the federal response will only be needed through home team support or with limited on-scene response. The federal response would be tailored to the situation and the requests from the local and state governments.

0–2 h: Initial stages of the incident where little is known. The only information that might be known is that detection equipment is showing the presence of radiation.

During the first few hours of a radiological emergency local authorities will have to coordinate the response. They will have to rely on their own first responders to deal with the situation in the field. It is imperative that the incident commander and/or local officials execute protective actions as soon as possible to minimize doses to the public. The local government can request assistance for the federal government. During the very early stages of the response this assistance would take the form of advice and predictive modeling so the local officials and responders can better address the situation.

- *Local Response:* Local first responders would take charge of the scene and attempt to bring the situation under control and deal with any victims. Depending on the complexity of the response, local fire and rescue may rely heavily on their own Hazardous Material (HAZMAT) units. Immediate decisions on public protection will be from the on-scene Incident Commander. Once established, the local Emergency Operations Center (EOC) and senior public official will evaluate the situation and decide if further protective actions are necessary

Federal Response

- *Consequence Management Home Team:* Experts that are available through video/teleconference or bridge lines to provide aid to local responders or officials. This aid can take the form of scientific support, data management, event visualization through Geographic Information Systems (GIS) and logistics. This asset would be available throughout the incident to help coordinate the response and aid field assets
- *National Atmospheric Release Advisory Center (NARAC):* This asset utilizes a complex atmospheric dispersion model to predict the release of the material. In the early stages it may only use a “smoke” model if the source term is unknown. In this way responders and local official will be able to see the direction and possible extent of any releases. As more is known about the incident and environmental measurements are accumulated, NARAC will refine its models to give a better representation of the situation. Working in conjunction with the CMHT, maps can be produced and provided to local officials allowing them a better idea of what protective actions should be in place and how to respond to the event (Fig. 2). This asset is used throughout the incident.
- *Remote Advisory Team (Remote A-Team):* Representatives of federal agencies available through the CMHT that may provide additional advice on the situation. Members of the A-Team includes representatives from the EPA, Department of Agriculture (USDA), Food and Drug Administration (FDA), the Center for Disease Control (CDC) and other federal agencies as needed.

Fig. 1 Visual representations of the time of a radiological emergency response. Department of Energy (2019) Federal Radiological Monitoring and Assessment Center (FRMAC): Federal Outreach, DOE/NV/03624-0615. Las Vegas, NV: Department of Energy/NV.

Fig. 2 Example map product produced by the CMHT with modeling data from NARAC. This map would be produced in the early phase of the incident and give decision makers an idea of areas where evacuation or sheltering may be warranted based on Federal guidelines. Department of Energy (2019) Federal Radiological Monitoring and Assessment Center (FRMAC): Federal Outreach, DOE/NV/03624-0615. Las Vegas, NV: Department of Energy/NV.

- **Radiation Emergency Assistance Center/Training Site (REAC/TS):** Experts in the areas of medical treatment and evaluation from situations involving radiation exposure. In the early stages of the incident they would be available for consultation with medical professional, first responders and local officials. They would be available throughout the response primarily in the form of remote support. However, they do have a small deployable team that could respond.

1–6 h: Still early stages of the incident. Little may be known about the source term or extent of the emergency.

- **State:** The State may have resources such as experts or monitoring teams that can help local responders and officials.
- **Civil Support Team (CST):** These are Department of Defense (DOD) assets that are associated with the state's National Guard and are trained in Chemical, Biological, Radiological/Nuclear (CBRN) response. All states have at least one CST. These teams can deploy and provide assistance to local responders and medical personnel. Because they are a regional asset, they would be one of the first teams to arrive. The CST is a governor controlled state capability.
- **Radiological Assistance Program (RAP):** This is a regional team sponsored by the DOE and deploys from various DOE sites throughout the United States. It is a regional asset and can be on the scene early in the radiological emergency. A RAP team can deploy with up to 8 members to conduct field monitoring and sampling measurements in addition to providing radiological advice to protect the health and safety of responders and the public.

Support for most events typically ends here. The event is localized and only minimal advice and support is needed. However, if the event is larger or more complex, additional federal assets will be on the way. The initial teams are working with incident command. They are taking radiological data with specialized instruments and transmitting that data back to the CMHT. While the source term might not be completely known, most likely at least some of the deposited isotopes have been identified through field-gamma spectroscopy. The presence of alpha and beta radiation would also be known, but the identification of those isotope may not be possible without laboratory analysis. This type of analysis could take days to weeks. All data being collected in the field is ultimately used by NARAC to continually refine dispersion models so that the release can be better defined (Figs. 3 and 4).

6–12 h: The initial event may or may not be under control. Initial PAGs are in-place.

- **Aerial Measuring System (AMS):** This DOE asset is comprised of fixed-wing aircraft and helicopters. They are stationed in two locations in the United States: Las Vegas, NV and Washington, DC. Depending on their proximity to the event it could take

Fig. 3 NARAC can you use field measurements and data from other sources to refine dispersion models throughout an event. This map shows dose rate estimates 36 hours post-event and is a result of NARAC using more available data to better refine their prediction. Department of Energy (2019) Federal Radiological Monitoring and Assessment Center (FRMAC): Federal Outreach, DOE/NV/03624-0615. Las Vegas, NV: Department of Energy/NV.

several hours for them to arrive. The fixed-wing aircraft will arrive first because it is faster. AMS employs specialized airborne radiation detection systems and provide real-time, geo-located measurements of air and ground contamination. The advantage of aerial systems is that they can rapidly cover large areas and are not constrained by roadways. The fixed-wing has limited detection capability in that it must fly higher and faster than the helicopter and therefore gives a less defined visual indication of the ground contamination. The helicopter because it can fly lower and slower performs detailed surveys and can detect lower levels of radioactivity. **Fig. 4** is an AMS map produced during the Fukushima Daiichi disaster in 2011. The surveyed area covers urban and isolated areas out almost 50 miles from the plant. A color legend allows the viewer to know the exposure rate on the surface.

- **Consequence Management Advance Command (CMAC):** This is an advance team that helps facilitate the integration of a large team that will soon arrive called the Consequence Management Response Team (CMRT). The CMAC deploys directly to the local command centers established to manage the incident. The CMAC is comprised of the primary CMRT management team and tasked to establish the consequence management planning element in the site Incident Command Post (ICP) or designated incident management node where response planning is taking place.
- **REAC/TS:** If the field element of REAC/TS has been requested it is expected it would arrive during this period.
- **CBRN Enhanced Response Force Packages (CERFPs):** If the incident has caused mass damage and requires specialized victim recovery/rescues the CERFPs may be activated by the state's governor. Like the CST this team is part of a state's National Guard. CERFPs employ search and extraction, casualty decontamination, Fatality Search and Recovery Team (FSRT), and emergency medical triage and treatment capabilities to maximize the lifesaving response to a WMD attack or other CBRN incident.

12–24 h: The initiating event may still not be under control. By this time the gamma emitting nuclides should be known. AMS data may be available. If the event has stabilized the extent of the contamination may be known. Data has continually been fed back to NARAC and more refined prediction maps have been generated. Few monitoring teams are on the ground and a full characterization of the deposition has not occurred.

- **CMRT** – A large response team of 50 to 100 scientists, technicians, health/safety professionals and logistics support staff. They will come equipped with several pallets of equipment to support the response. The assembled team and equipment will include:
 - Assessment scientists to support data evaluation and visualization and support public and responder safety calculations

Fig. 4 Aerial measurement system data from the response to the Fukushima Daiichi nuclear power plant accident. Department of Energy (2019) Federal Radiological Monitoring and Assessment Center (FRMAC): Federal Outreach, DOE/NV/03624-0615. Las Vegas, NV: Department of Energy/NV.

- o Geographical Information Systems (GIS) equipment and personnel for creating map products to visualize data and potential extents
 - o Health and Safety specialists to support responders
 - o Field teams to assist with data and sample collection
 - o Contamination control to support field team activities
 - o Sample control personnel to catalog and manage sample collection and analysis
 - o Logistics support for FRMAC teams
- *Fly Away Laboratory (FAL)*: This is a mobile laboratory set-up that can be established in the field. It has limited sample analysis capability, but can conduct gamma spectroscopy and gross alpha/beta counting. It can have no radiochemistry capabilities, but will conduct limited sample screening and prioritization for fixed laboratories that are supporting the event.

24–48 h: Characterization of the deposited material is still taking place. Other agency response teams have arrived and are integrating into a unified response.

- *Federal Radiological Monitoring and Assessment Center (FRMAC)*: Sometime after 24 h and if multiple federal agencies respond to the incident a FRMAC will be formed. This allows the US government to have unified monitoring and assessment activities that efficiently work together to meet the objectives of the response set by incident command and the state. The FRMAC is organized by the DOE regardless of the agency that is managing the overall response. All federal teams that have responded or will respond to the incident will fold under the FRMAC so that the radiological assessment will be an organized endeavor.
- *A-Team*: Members of the A-team will be on site to directly support response to advise incident command and decision makers.

By this time the incident is potentially fully manned. Addition staffing and equipment may still be necessary, but the infrastructure is in-place to request and integrate any needed materials, equipment and personnel. Portions of Table 6 below are pulled directly from the NRIA and list other agencies and teams that may join the response as the emergency progresses.

Table 6 Additional assets, resources and teams that may join a radiological emergency response.

<i>Organization</i>	<i>Resource name</i>	<i>Description</i>
DHS (FEMA)	Radiological Operations Support Specialist Concept	Provides technical radiological/nuclear support to Incident Command at the state Emergency Operations Center level
DHS (FEMA)	RadResponder Network	A free Cloud-based radiological/nuclear data collection; management; and analysis tool for local, state, federal, tribal, and territorial governments. Assists with radiological/nuclear incident characterization and situational assessment. Provides a common framework to rapidly and accurately collect, aggregate and share radiological monitoring and sampling data; manage specialized equipment and personnel; and track radiological response teams during an emergency. The RadResponder Network can be accessed on computers and smart phone/tablet devices
DOE (NSA)	Nuclear Weapons Accident Response Group	Provides technical guidance and responds to U.S. nuclear weapons accidents. The team assists in assessing weapons damage and risk, and in developing and implementing procedures for safe weapon recovery, packaging, transportation, and disposal
DOJ (FBI)	Evidence Response Team Unit (ERTU): Hazardous Evidence Response Team (HERT)	Provides training, leadership, and subject matter expertise in hazardous evidence collection, as well as in the management and processing of forensic evidence in CBRN crime scenes. ERTU also provides coordination and oversight for operational response and activities of FBI field office HERTs
EPA	Airborne Spectral Photometric Environmental Collection Technology (ASPECT)	The ASPECT aircraft is managed by EPA's CBRN Consequence Management Advisory Team and provides remotely sensed chemical/radiological (gamma and neutron) data and imagery (situational awareness). It can identify, quantify, and map chemical plumes and ground-based radiation. It is also capable of collecting high-resolution digital photography and video products. Data products are transferred to ground base support within minutes of collection through satellite communications, while in flight
EPA	CBRN Consequence Management Advisory Team (CMAT)	Provides scientific and technical support for all phases of environmental response to a CBRN incident, including health and safety site characterization, environmental sampling and analysis, environmental monitoring, risk assessment building and structure decontamination, waste treatment environmental cleanup, and clearance; manages the EPA's ASPECT fixed-wing aircraft, which provides chemical/radiological data; deploys and operates ground-based characterization and mapping capability for radiological incidents (CMAT Asphalt)
EPA	Environmental Response Team	Provides scientific and technical expertise, including health and safety, environmental sampling, air monitoring, toxicology, risk assessment, waste treatment, contaminated water/scientific divers; and site decontamination and remediation; provides field-analytical and real-time air monitoring with the EPA mobile laboratories known as Trace Atmospheric Gas Analyzers
EPA	Radiation Task Force Leaders (RTFLs)	A sampling and monitoring force multiplier comprised of EPA Response Support Corps members based throughout EPA's Regions and Labs. The RTFLs are specially trained EPA personnel who will lead small teams of personnel in performance of tasks including field radiological measurements, contamination monitoring, soil sampling, air sampling, decontamination line setup and support, radiological control area support, and dose management support

(Continued)

Table 6 Additional assets, resources and teams that may join a radiological emergency response.—cont'd

<i>Organization</i>	<i>Resource name</i>	<i>Description</i>
EPA	RadNet	Monitors the nation's air, precipitation, and drinking water to track radiation in the environment. RadNet sample testing and monitoring results show the fluctuations in normal background levels of environmental radiation. The RadNet system will also detect higher than normal radiation levels during a radiological incident. During a radiological incident, officials use RadNet data to help make science-based decisions about protecting the public. Scientists use RadNet air monitoring data to help estimate the potential radiation dose to people
EPA	Radiological Emergency Response Team	Provides advice on protective measures to ensure public health and safety; assessments of dose and impact of release to public health and the environment; monitoring, sampling, laboratory analyses, and data assessments to assess and characterize environmental impact; and technical advice and assistance for containment, cleanup, restoration, and recovery
EPA	Radiological Environmental Assessment Equipment	Sample preparation trailers and mobile laboratories carry electrical generators and supplies for approximately 1 week; not applicable for other assets
HHS (CDC)	Strategic National Stockpile Agents for Nuclear/Radiological Incidents	National repository of antibiotics, chemical antidotes, antitoxins, life support medications, IV administration, airway maintenance supplies, and medical/surgical items. Nuclear/radiological-specific resources include chelating agents (Calcium and Zinc Diethylenetriamine pentaacetate), Prussian Blue, and Growth Factors/Cytokines for White Blood Cells
U.S. Department of Veteran's Affairs	Medical Emergency Radiological Response Team (MERRT)	The MERRT responds to radiological disasters that require medical assistance and/or radiological decontamination of victims. The MERRT provides medical assistance including direct patient treatment, assisting and training local health care providers in managing, handling, and treatment of radiation-exposed and contaminated casualties; assesses the impact on human health; and provides consultation and technical advice to local, state, and federal authorities

This information was taken directly from the NRIA (DHS, 2016).

Conclusion

Radiation protection in an emergency response is a complex undertaking. A radiation release can be limited to a localized event or result from a major release affecting thousands of square miles and millions of people. In all cases the goal of the response is the same for radiation protection: limit doses to the public and responders. Emergencies are broken into phases and each phase has specific goals in terms of dose control. In the early phase protective actions, based on EPA suggested guidelines, are implemented to primarily avoid doses that will cause short term effects such as radiation sickness. This is accomplished through sheltering-in-place or evacuation. After the early phase, protective actions are used to avoid doses that can lead to long-term effects like cancer. It is important to remember that when protective actions are limited you are only reducing the risk of radiation affects. Other risks that result from the actions may be greater and should be carefully considered before implementing any actions.

The federal government has issued tools and documentation to aid in the implementation of protective actions. One of the most useful documents that associates doses with protective actions is EPA400. The values listed in the document are only meant as guides to allow flexibility of implementing protective actions when considering the complexity and uniqueness of the specific radiological event. To assess and predict doses Turbo FRMAC was created so the experts can interpret radiological data and associate them to EPA 400 guidance. This chapter only presented a limit number of available resources and further research by the reader may yield other guidance and tools for areas of interest.

One of the most important aspects of radiation protection in emergency response is that you are not alone in the event. There are several state and federal resources that are only a phone call away and free to use. Most situations can be handled by local first responders and HAZMAT teams. However, situations may arise when advice or additional field support is needed. This aid can come in the form of advice over the phone to hundreds of technical experts responding on-site. This chapter listed a majority of these teams, but other teams might exist that would be available specific emergencies.

Introduction

This chapter presents an overview of standards to protect workers and the public from the harmful effects of ionizing radiation. The following topics are discussed:

- Health effects of concern in radiation protection;
- Basic principles of radiation protection;
- Radiation protection standards recommended by the International Commission on Radiological Protection (ICRP) and by the National Council on Radiation Protection and Measurements (NCRP) in the United States (U.S.)¹;
- Current standards established by regulatory authorities in the U.S.

Discussions of ICRP and NCRP recommendations summarize their development in several iterations over the last six decades. Although each set of new recommendations superseded those developed previously, an historical perspective is important when current standards in the U.S. incorporate some elements of all recommendations from the late 1950s to the present.

Health effects from radiation exposure

Two types of health effects, called stochastic effects and tissue reactions, are of concern in radiation protection.

Stochastic effects are effects for which the probability of occurrence, but not their severity, is a function of dose, without threshold. These effects are random in nature and can result from misrepair of damage in a single cell nucleus. The most important stochastic effects from radiation exposure are solid cancers and leukemias. Heritable effects in descendants of exposed individuals also are regarded as stochastic.

Tissue reactions, also called nonstochastic or deterministic effects, are effects for which the severity varies with dose and a threshold usually exists. These effects occur when many cells in an organ or tissue are damaged, resulting in a loss of tissue

¹ICRP and NCRP are nongovernmental organizations of radiation protection professionals whose recommendations have been incorporated in laws and regulations in many countries.

function. Examples of tissue reactions from radiation exposure include cataract of the lens of the eye, reddening of the skin, depletion of white blood cells from irradiation of bone marrow, and impairment of fertility from irradiation of the gonads (testes and ovaries).

To protect against the two types of health effects, radiation protection standards have two basic objectives:

- [1] Limitation of the risk (probability) of stochastic effects;
- [2] Prevention of tissue reactions.

Principles of radiation protection

The system of radiation protection developed by ICRP and NCRP is based on three principles:

- [1] Justification of exposures;
- [2] Optimization of protection;
- [3] Limitation of dose to individuals.

The principles of justification and optimization apply to all situations in which radiation exposures can be controlled in some manner. The principle of dose limitation applies to planned (routine) exposures only, that is, to situations involving the deliberate introduction and operation of radiation sources.

Current statements of the basic principles (ICRP, 2007) are summarized as follows:

- **Justification:** Any decision that alters the radiation exposure situation—that is, any decision to introduce a new radiation source, reduce an existing exposure, or reduce the risk of potential exposure—should do more good than harm (positive net benefit to an individual or society).
This principle is important, for example, in ensuring that the benefit to patients from uses of radiation in medicine outweighs the associated health risks. It also is the basis for bans on frivolous uses of radioactive materials in jewelry and children's toys.
- **Optimization:** The likelihood of incurring exposures, the number of people exposed, and the magnitude of their individual doses should all be kept as low as reasonably achievable (ALARA), taking into account economic and societal factors.
When exposures are optimized, doses to individuals can vary greatly depending on the situation (e.g., doses to the public from routine emissions from nuclear power plants vs radon in homes).
- **Dose limitation:** The total dose to any individual in planned exposure situations other than medical exposure of patients should not exceed appropriate limits.
Dose limits are intended to ensure that doses and associated health risks to the most highly exposed individuals in planned exposure situations do not exceed levels regarded as acceptable.

ICRP and NCRP recommendations on radiation protection standards

This section discusses recommendations on radiation protection standards for workers and the public developed by ICRP and NCRP over the last six decades. Elements of recommendations from the late 1950s and their subsequent revisions are incorporated in many current standards established by regulatory authorities in the U.S. Recommendations prior to that time are discussed elsewhere (Taylor, 1971, 1979; Kocher, 1991).

ICRP publications 1 and 2; NCRP report nos. 22 and 39

Standards for workers

ICRP Publications 1 and 2 (ICRP, 1959, 1960) and NCRP Report No. 22 (NCRP, 1959) presented recommendations on maximum permissible dose to workers, which were intended to limit doses to the whole body or critical organ (usually the organ or tissue receiving the highest dose) from external exposure and from internal exposure due to inhalation and ingestion of radionuclides combined.²

Recommended maximum permissible doses to the whole body, gonads, blood-forming organs, and lens of the eye in workers included:

²In previous recommendations, ICRP and NCRP developed limits on external and internal exposure of workers separately. The recommendation that dose limits for the whole body or critical organ should apply to doses from external and internal exposure combined was not incorporated in radiation protection standards for workers and the public established by the U.S. Atomic Energy Commission in 1960 and was not adopted in the U.S. until standards to limit exposures of the public to radionuclides released in operations of uranium fuel-cycle facilities were established in 1977 (see Table 3).

- a cumulative (total) dose equivalent^{3,4} at age N of 50(N–18) mSv⁵;
- to the extent permitted by the limit on cumulative dose, a dose equivalent in any 13-week period (quarter) of 30 mSv.

The limit on cumulative dose implied a limit on average annual dose equivalent of 50 mSv. The greater importance of the limit on cumulative dose was based on the view that total dose was more important than dose rate in determining risks from radiation exposure, provided that dose rates were sufficiently low to prevent tissue reactions and only small exceedances of the implied limit on average annual dose occurred in any year (Taylor, 1971, 1979).

Maximum permissible doses given above were substantially lower than previous ICRP and NCRP recommendations (Kocher, 1991). Reductions in dose limits for workers were based on two considerations: (1) the assumed genetic hazard (heritable effects) from irradiation of the gonads and the large increase in the worker population in the nuclear weapons industry; and (2) a desire to reduce possible increases in leukemias, which were first observed in radiologists in the mid-1920s (Taylor, 1971, 1979).

ICRP and NCRP also recommended higher maximum permissible doses to other organs and tissues, which, along with the dose limits for the lens of the eye, were mainly intended to prevent tissue reactions.

In Report No. 39 (NCRP, 1971), NCRP retained the limit on cumulative dose equivalent of 50(N–18) mSv, but the limit of 30 mSv in any quarter was replaced by a limit on annual dose equivalent of 50 mSv. NCRP also recommended (1) higher limits on annual dose equivalent to the skin, forearms, hands, and other organs or tissues to prevent tissue reactions and (2) a limit on dose equivalent during the entire gestation period of pregnant women of 5 mSv to protect the embryo/fetus.

Standards for the public

Recommendations on radiation protection standards for the public were developed beginning in the mid-1950s, when ICRP recommended that dose limits for the public, excluding natural background and medical exposures, should be one-tenth of limits for workers (ICRP, 1955). This recommendation was based on the consideration that, unlike workers, the public receives no direct benefit associated with their exposures (Taylor, 1979).

Based on dose limits for workers in Publications 1 and 2 (ICRP, 1959, 1960), ICRP's recommended limit on annual dose equivalent from whole-body exposure of the public was 5 mSv. ICRP also recommended a limit on average dose equivalent to the gonads in large population groups—the so-called genetically significant dose to the population—of 50 mSv in 30 years. This recommendation, which addressed the concern about heritable effects from radiation exposure, implied a limit on average annual dose equivalent to the gonads of 1.7 mSv.

NCRP also recommended a limit on annual dose equivalent from whole-body exposure of the public of 5 mSv (NCRP, 1959). This dose limit was retained in Report No. 39 (NCRP, 1971), which also included a limit on average annual dose equivalent to the whole body and gonads in the population of the U.S. of 1.7 mSv.

ICRP publication 26; NCRP report no. 91

Recommendations in ICRP Publication 26 (ICRP, 1977) included two important developments. First, limits on dose equivalent to the whole body, gonads, and blood-forming organs were replaced by limits on effective dose equivalent, defined as a weighted average of dose equivalents to six organs or tissues and a remainder category comprised of the five other organs or tissues receiving the highest dose equivalents. By this change, doses to many organs or tissues could be accounted for in limiting risks of stochastic effects, especially when nonuniform irradiation of the whole body from internal exposure occurred.

The tissue weighting factor (w_T) for an organ or tissue used in calculating effective dose equivalents as a weighted average of dose equivalents was intended to represent the fractional contribution from exposure of that organ or tissue to the total risk of cancer mortality or severe heritable effects when the whole body was irradiated uniformly. By use of the effective dose equivalent, doses from external and internal exposure, whether from uniform or nonuniform irradiations of the whole body, could be combined on a common risk basis.

Second, ICRP no longer considered that the genetic hazard was the primary concern in radiation protection. By adopting a w_T for the gonads of 0.25, the risk of severe heritable effects from uniform whole-body irradiation was assumed to be one-third of the risk of cancer mortality. The reduction in the importance of the genetic hazard was based mainly on radiobiologic data in mice and data in offspring of Japanese atomic-bomb survivors.

ICRP also developed estimates of risk coefficients (risks per Sv) for stochastic effects. Risk coefficients for organs and tissues other than the gonads were based mainly on data on cancer mortality in Japanese atomic-bomb survivors. ICRP assumed a nominal risk coefficient for cancer mortality from uniform whole-body irradiation of 10^{-2} Sv^{-1} .

Standards for workers

Recommended dose limits for routine exposure of workers in ICRP Publication 26 (ICRP, 1977) included:

³Terms related to radiation dose, quantities used in radiation protection, and their units in this chapter are defined in ICRP and NCRP reports referenced in this chapter.

⁴Dose equivalent averaged over an organ or tissue is now called equivalent dose (ICRP, 1991, 2007).

⁵Prior to introduction of SI units in radiation protection, absorbed dose was given in rads (1 rad = 0.01 Gy) and dose equivalent was given in rems (1 rem = 0.01 Sv).

- an annual effective dose equivalent of 50 mSv to limit stochastic effects;
- annual dose equivalents of 0.3 Sv to the lens of the eye and 0.5 Sv to all other organs and tissues to prevent tissue reactions;
- once a pregnancy was diagnosed, an annual effective dose equivalent to the mother of 15 mSv to protect the embryo/fetus.

The limit on annual effective dose equivalent was consistent with the previous limit on cumulative dose equivalent to the whole body at age N of $50(N-18)$ mSv. However, ICRP no longer recommended a limit on cumulative dose.

For planned special exposures that occur infrequently, ICRP recommended limits on effective dose equivalent of 100 mSv in single event and 250 mSv over a working lifetime.

Based on data in other safe occupations, ICRP judged that risks to workers would be acceptable if the average annual mortality risk did not exceed 10^{-4} . At ICRP's nominal risk coefficient for cancer mortality of 10^{-2} Sv^{-1} , the limit on annual effective dose equivalent of 50 mSv corresponded to an annual mortality risk about an order of magnitude higher than the average risk judged to be acceptable. However, the annual limit of 50 mSv was justified on the grounds that application of the ALARA principle had resulted in average annual doses to workers of about 5 mSv, so the risk of mortality for an average worker would be acceptable.

Recommended dose limits for routine exposure of workers in NCRP Report No. 91 (NCRP, 1987) included:

- an annual effective dose equivalent of 50 mSv;
- a total effective dose equivalent at age N of $10 \times N$ mSv;
- annual dose equivalents of 0.15 Sv to the lens of the eye and 0.5 Sv to all other organs or tissues;
- a total dose equivalent to the embryo/fetus (excluding medical exposure) of 5 mSv, and a dose equivalent of 0.5 mSv in any month once a pregnancy was known.

The limit on total effective dose equivalent, which replaced the previous limit of $50(N-18)$ mSv, was intended to limit the lifetime risk of fatal stochastic effects to $< 10^{-2}$.

NCRP also recommended that (1) the effective dose equivalent from rare planned special exposures should not exceed 100 mSv in a single event and over a working lifetime and (2) only actions involving life-saving justify acute exposures > 100 mSv in emergency situations.

Standards for the public

Recommended dose limits for routine exposure of the public in ICRP Publication 26 (ICRP, 1977) included (1) an annual effective dose equivalent of 5 mSv and (2) an annual dose equivalent to any organ or tissue of 50 mSv. In developing the limit on annual effective dose equivalent, ICRP judged that the risk of stochastic effects from exposure of the public should not exceed other risks the public accepts in everyday life, that is, an annual risk of mortality in the range of 10^{-6} to 10^{-5} . At ICRP's nominal risk coefficient for cancer mortality of 10^{-2} Sv^{-1} , the limit on annual effective dose equivalent for the public should have been about 1 mSv. However, the annual limit of 5 mSv was adopted based on a judgment that average annual doses to the public normally should be less than 0.5 mSv.

In a later clarification, ICRP (1985) emphasized that:

- the principal dose limit for the public was an annual effective dose equivalent of 1 mSv;
- a subsidiary limit of 5 mSv could be applied in some years if the annual effective dose equivalent averaged over a lifetime did not exceed 1 mSv.

Recommended dose limits for routine exposure of the public in NCRP Report No. 91 (NCRP, 1987) included:

- annual effective dose equivalents of 1 mSv for continuous or frequent exposure and 5 mSv for infrequent exposure;
- an annual dose equivalent to the lens of the eye, skin, and extremities of 50 mSv.

NCRP also recommended a remedial action level for indoor radon in dwellings, which was assumed to correspond to an annual effective dose equivalent of 20 mSv and was expected to limit the annual risk of lung cancer to about 4×10^{-4} .

Based on the assumed reduction in the importance of severe heritable effects, ICRP and NCRP did not retain their previous recommendations on limiting the genetically significant dose to the whole population at about one-third of the dose limit for individuals.

ICRP publication 60; NCRP report no. 116

In ICRP Publication 60 (ICRP, 1991), the effective dose equivalent was replaced by the effective dose, which differed in two important ways. First, dose equivalents to six additional organs and tissues were included in the remainder category.

Second, tissue weighting factors (w_T) used in calculating effective doses were intended to represent the fractional contribution from exposure of each organ or tissue to the total detriment, rather than risk, from uniform whole-body irradiation. Total detriment was calculated from estimated risks of cancer mortality or severe heritable effects by accounting for (1) lethality fractions for cancers in each organ or tissue (i.e., a weight was assigned to nonfatal cancers relative to fatal cancers) and (2) the relative years of life lost due to a cancer death attributable to radiation and the relative years of impaired life due to nonfatal cancers and heritable effects.

In Publication 60, ICRP developed nominal probability (risk) coefficients for cancer mortality from uniform whole-body irradiation of $4 \times 10^{-2} \text{ Sv}^{-1}$ in workers and $5 \times 10^{-2} \text{ Sv}^{-1}$ in the whole population.

Standards for workers

Recommended dose limits for routine exposure of workers in ICRP Publication 60 (ICRP, 1991) included:

- an annual effective dose averaged over defined periods of 5 years of 20 mSv and an effective dose in any year of 50 mSv;
- annual equivalent doses of 0.15 Sv to the lens of the eye and 0.5 Sv to localized areas of the skin and the hands and feet;
- once a pregnancy was declared, an equivalent dose to a woman's abdomen from external exposure of 2 mSv for the remainder of pregnancy and a committed effective dose from intakes of radionuclides of about 1 mSv.

The limit on annual effective dose averaged over defined 5-year periods was based on a judgment that a lifetime effective dose to workers > 1 Sv (probability of attributable death $> 4 \times 10^{-2}$) would be unacceptable.

In emergency situations, ICRP recommended that the effective dose should not exceed 0.5 Sv and the equivalent dose to the skin should not exceed 5 Sv, except in life-saving actions.

Recommended dose limits for routine exposure of workers in NCRP Report No. 116 (NCRP, 1993) are summarized as follows:

- Limits on annual and total effective dose were the same as the previous limits on effective dose equivalent in Report No. 91.
- The previous limit on annual equivalent dose to the lens of the eye was retained, but the higher limit of 0.5 Sv applied to the skin and the hands and feet only.
- The previous monthly limit on equivalent dose to the embryo/fetus once a pregnancy was known was retained, but the limit on total equivalent dose was not.

NCRP also adopted ICRP's recommended dose limits in emergency situations given above.

Standards for the public

Recommended dose limits for routine exposure of the public in ICRP Publication 60 (ICRP, 1991) and NCRP Report No. 116 (NCRP, 1993) were essentially the same:

- annual effective doses of 1 mSv for continuous or frequent exposure and 5 mSv for infrequent exposure;
- annual equivalent doses of 15 mSv to the lens of the eye and 50 mSv to the skin.

NCRP also applied the dose limit for the skin to the hands and feet.

The principal limit on annual effective dose of 1 mSv recommended previously was retained even though the nominal probability coefficient for cancer mortality in the whole population was a factor of five higher than the previous assumption. This decision was based on two considerations. First, widespread use by regulatory authorities of restrictions on doses from specific sources at a fraction of the annual limit of 1 mSv had reduced the highest doses to the public to levels well below the limit. Second, an annual limit of 1 mSv was comparable to variations in unavoidable doses from natural background in different locations, which the public generally did not consider in deciding where to live.

NCRP retained its previous remedial action level for exposure to indoor radon. For radon in dwellings, ICRP recommended an action level when a remedial action was simple that was assumed to correspond to an annual effective dose of about 20 mSv.

ICRP publication 103; NCRP report no. 180

In its current recommendations in Publication 103 (ICRP, 2007) [see also ICRP (2006)], ICRP addressed three exposure situations: (1) planned, (2) emergency, and (3) existing. In addition to dose limits, which apply in planned (routine) exposure situations only, ICRP recommended so-called dose constraints in planned exposures to specific sources and reference levels in emergency and existing exposure situations, which should be used as restrictions (starting points) in applying the ALARA principle. Use of dose constraints in planned exposure situations had been recommended previously (ICRP, 1991).

ICRP retained use of the effective dose and radiation detriment in its current recommendations. However, two important changes were made. First, the tissue weighting factor (w_T) for the gonads was reduced from 0.20 (the value in Publication 60) to 0.08. This reduction in the assumed importance of severe heritable effects compared with cancer was based mainly on an absence of clear evidence of such effects in offspring of Japanese atomic-bomb survivors.

Second, total radiation detriment was calculated from estimated risks of cancer incidence, rather than mortality, in different organs and tissues. However, by accounting for lethality fractions for different cancers and the relative years of life lost due to a cancer death or severe heritable effect, ICRP still regards cancer mortality as the primary stochastic effect of concern in radiation protection.

Standards for workers

Recommendations on protection of workers in planned exposure situations in ICRP Publication 103 (ICRP, 2007) are summarized as follows:

- The previous limits on (1) annual effective dose of 20 mSv averaged over defined periods of 5 years and 50 mSv in any year and (2) annual equivalent dose to the lens of the eye (0.15 Sv) and to the skin and hands and feet (0.5 Sv) are retained.
- The equivalent dose to the embryo/fetus for the remainder of pregnancy in declared pregnant women should not exceed 1 mSv.
- Dose constraints for specific sources should be ≤ 20 mSv annual effective dose.

ICRP's recommendations for other exposure situations include:

- In emergency situations, no restrictions on life-saving actions by informed volunteers if the benefit to others outweighs the risk to a rescuer; in actions not involving life-saving, reference levels of 1 or 0.5 Sv effective dose in urgent rescue operations and ≤ 0.1 Sv effective dose in other rescue operations;
- For existing exposures to radon at work, a reference level < 10 mSv annual effective dose (radon concentration in air < 1500 Bq m⁻³).⁶

Recommendations on protection of workers in planned exposure situations in NCRP Report No. 180 (NCRP, 2018) are summarized as follows:

- The previous limits on annual effective dose of 50 mSv, total effective dose at age N of $10 \times N$ mSv, and monthly equivalent dose to the embryo/fetus once a pregnancy is declared of 0.5 mSv are retained.
- The previous limit on annual equivalent dose to the skin and extremities is retained but is expressed as a radiation-weighted absorbed dose of 0.5 Gy⁷; the limit for the lens of the eye is 50 mGy.
- A worker's estimated annual and total effective dose should include the contribution from exposure to radon if the concentration of radon in air in the workplace, after application of mitigation measures, remains above 300 Bq m⁻³.

NCRP's recommendations for emergency exposure situations include:

- to prevent acute life-threatening effects, an absorbed dose to the whole body from photons < 0.5 Gy;
- in all activities other than life-saving or prevention of catastrophic conditions, an effective dose for the duration of an emergency operation < 0.1 Sv.

Standards for the public

Recommendations on protection of the public in planned exposure situations in ICRP Publication 103 (ICRP, 2007) include:

- a limit on annual effective dose of 1 mSv, with a higher effective dose allowable in a single year in special circumstances if the average annual effective dose over 5 years does not exceed 1 mSv;
- limits on annual equivalent dose of 15 mSv to the lens of the eye and 50 mSv to the skin;
- dose constraints for specific sources ≤ 1 mSv annual effective dose (e.g., ≤ 0.3 mSv for radioactive waste disposal, ≤ 0.1 mSv for prolonged exposure to long-lived radionuclides);
- dose constraints for volunteers in biomedical research ranging from < 0.1 mSv effective dose if the benefit to society is minor to > 10 mSv if the benefit is substantial;
- a dose constraint for comforters and care-givers of patients undergoing diagnosis or treatment of 5 mSv effective dose per episode.

In most emergency exposure situations, ICRP recommends a reference level for the public of 20 to 100 mSv annual effective dose for all planned countermeasures combined.

ICRP's recommendations for existing exposures of the public include:

- for exposure to radon at home, a reference level < 10 mSv annual effective dose (radon concentration in air < 600 Bq m⁻³);
- for exposure to naturally occurring radioactive material (NORM), natural background radiation, and radioactive residues in human habitats, a reference level of 1 to 20 mSv annual effective dose.

Recommendations on protection of the public in planned exposure situations in NCRP Report No. 180 (NCRP, 2018) include:

- limits on annual effective dose of 1 mSv for continuous or frequent exposure and 5 mSv for infrequent exposure;
- limits on annual radiation-weighted absorbed dose of 15 mGy to the lens of the eye and 0.5 Gy to the skin and extremities;
- for volunteers in biomedical research, an effective dose ranging from < 0.1 mSv if the benefit to society is minor to > 0.1 Sv if the benefit to the individual is very substantial;
- for comforters and care-givers of patients undergoing diagnosis or treatment, the effective dose should not exceed 5 mSv per episode.

NCRP's recommendations for existing exposures of the public are summarized as follows:

- Concentrations of radon in air in dwellings should be < 300 Bq m⁻³ (expected to correspond to an annual effective dose of 1 to 20 mSv, depending on the exposure time).
- In exposure situations not previously subject to control, including exposure to elevated levels of NORM whether enhanced by human activities or not, the effective dose in the first year should not exceed 20 mSv, and the effective dose in later years should be reduced further by applying the ALARA principle.

⁶Prior to introduction of SI units in radiation protection, activity was given in curies (Ci) ($1 \text{ Ci} = 3.7 \times 10^{10} \text{ Bq}$).

⁷Weighting factors for densely ionizing radiations (e.g., neutrons, alpha particles, heavy ions) recommended in NCRP Report No. 180 are less than radiation weighting factors (w_R s) for stochastic effects used in calculating equivalent dose in an organ or tissue.

The latter recommendation also applies to exposure of the public to radioactive material introduced into the environment intentionally or by accident.

Current U.S. standards

Federal standards to control radiation exposures of workers and the public in the U.S. are established by the Nuclear Regulatory Commission (NRC), Department of Energy (DOE), and Environmental Protection Agency (EPA). NRC and DOE establish enforceable standards under authority of the Atomic Energy Act that apply to NRC licensees or to DOE and its contractor organizations only.⁸ EPA develops guidance to all federal agencies on radiation protection standards and establishes enforceable standards or guidance for a wide variety of specific sources of radiation in the environment under authority of the Atomic Energy Act and several other laws.

Not discussed here are (1) standards established by state authorities that apply to sources not regulated by a federal agency (e.g., exposure of workers to radiation emitted by x-ray machines at privately owned facilities) and (2) a standard used by the National Aeronautics and Space Administration to protect crew members during activities in space (NASA, 2014).

Radiation protection standards for workers

NRC's current radiation protection standards for workers in Title 10, Part 20, of the Code of Federal Regulations (10 CFR 20), first established in 1991, are based mainly on federal guidance developed by EPA (Office of the President, 1987), which incorporated recommendations in ICRP Publication 26 (ICRP, 1977). DOE's current radiation protection standards for workers in 10 CFR 835, first established in 1993, are based mainly on recommendations in ICRP Publication 60 (ICRP, 1991).

Radiation protection standards for workers in NRC and DOE regulations are summarized in Table 1. They differ from recent ICRP and NCRP recommendations by not including a limit on average annual dose over a defined period less than the dose limit in any year or a limit on total dose over a working lifetime.

Radiation protection standards for the public

Current radiation protection standards for the public in NRC and DOE regulations are summarized in Table 2. These standards apply to the total doses at a location from all sources that are under the control of the same organization. In NRC standards in 10 CFR 20 first established in 1991, limits on annual effective dose equivalent are based on recommendations in ICRP Publication 26 (ICRP, 1977). In DOE standards in Order 458.1 established in 2011, dose limits are based on recommendations in ICRP Publication 103 (ICRP, 2007).

Environmental radiation standards for specific sources

EPA, NRC, and DOE have established many enforceable standards or guidance to control exposures of the public to specific sources of radiation in the environment.⁹

Table 1 Radiation protection standards for workers established by NRC (10 CFR 20) and DOE (10 CFR 835).

Doses to workers shall be maintained as low as reasonably achievable (ALARA)
Dose limits for routine exposures ^a :
• annual effective dose equivalent or effective dose of 50 mSv
• annual dose equivalent or equivalent dose of 0.15 Sv to lens of the eye and 0.5 Sv to any other organ or tissue, including skin and extremities
• dose equivalent or equivalent dose to embryo/fetus from conception to birth in declared pregnant woman of 5 mSv
• weekly limit on intake of soluble uranium of 10 mg (NRC regulations only; consideration of chemical toxicity)
Dose limits for planned special exposures ^a :
• effective dose equivalent or effective dose of 50 mSv in any year and 250 mSv over a working lifetime ^b

^aNRC standards specify limits on effective dose equivalent or average dose equivalent in an organ or tissue (ICRP, 1977). DOE standards specify limits on effective dose or equivalent dose (ICRP, 1991).

^bAllowable doses in planned special exposures are in addition to allowable doses in routine exposures.

⁸NRC standards apply to exposures to (1) radioactive materials associated with operations at nuclear-fuel cycle facilities in the civilian sector and (2) certain accelerator-produced and naturally occurring radioactive materials. DOE standards apply to exposures associated with operations at any of its facilities, including operations related to the development and production of nuclear weapons.

⁹These standards and other standards and guidance, such as licensing criteria in NRC regulations, are discussed in more detail elsewhere (Kocher, 2008).

Table 2 Radiation protection standards for the public established by NRC (10 CFR 20) and DOE (Order 458.1).

Doses to the public shall be maintained as low as reasonably achievable (ALARA).

NRC's dose limits for routine exposures^a:

- annual effective dose equivalent of 1 mSv, excluding dose from permissible releases of radionuclides into sanitary sewerage
- annual effective dose equivalent up to 5 mSv with prior authorization
- dose equivalent in any unrestricted area from external sources of 0.02 mSv in any hour
- annual average concentrations of radionuclides in air and water in unrestricted areas based on annual effective dose equivalent of 0.5 mSv from inhalation or ingestion

DOE's dose limits for routine exposures^b:

- annual effective dose of 1 mSv, excluding dose from radon and decay products
- annual effective dose of 5 mSv with prior authorization, provided that average annual effective dose over any 5-year period does not exceed 1 mSv
- annual equivalent dose of 15 mSv to lens of the eye and 50 mSv to skin and extremities

^aNRC standards use effective dose equivalent and dose equivalent as defined in ICRP Publication 60 (ICRP, 1977).

^bDOE standards use effective dose and equivalent dose as defined in ICRP Publication 103 (ICRP, 2007).

Environmental radiation standards for specific sources established under the Atomic Energy Act are described in [Table 3](#). The various protection criteria represent exposure conditions judged to be reasonably achievable and, thus, are starting points for further application of the ALARA principle. Dose criteria in those standards are examples of dose constraints, which were used in environmental standards in the U.S. long before their use was recommended by ICRP (1991).

Environmental radiation standards and guidance established by EPA under laws other than the Atomic Energy Act are described in [Table 4](#). Except for standards for cleanup of contaminated sites under CERCLA, those standards and guidance were based on exposure conditions judged to be reasonably achievable using existing technology.

Standards for radioactivity in drinking water and cleanup of contaminated sites in [Table 4](#) differ in an important way from standards in [Table 3](#) (NCRP, 2004; Kocher, 2008). Standards established under the Atomic Energy Act are based on the principles of radiation protection described in the section "[Principles of radiation protection](#)." Those principles define a "top-down" approach to radiation protection, in which a limit on exposure that implicitly defines an upper bound on acceptable risk is prescribed and exposures are reduced below the prescribed limit by applying the ALARA principle.

The approach to regulation under the Safe Drinking Water Act and CERCLA is the opposite of the approach under the Atomic Energy Act. Those laws define a "bottom-up" approach to regulation, in which a risk goal is prescribed and an increase in risks above the goal is allowed based primarily on considerations of technical feasibility and cost.

Under the Safe Drinking Water Act, the goal for levels of all radionuclides in drinking water is zero, which cannot be achieved at any cost. Maximum contaminant levels (MCLs) in EPA regulations—the allowed relaxations above the goal—were based on existing levels in groundwater and surface waters and considerations of the costs and benefits to public health of reducing those levels.

The difference between the "top-down" and "bottom-up" approaches to regulation has been a particular source of confusion in decisions on cleanup of contaminated sites under CERCLA. Stakeholders in the public often assume that achieving a lifetime cancer risk in the range of 10^{-6} to 10^{-4} is a requirement, i.e., that any risk above that range is unacceptable. However, achieving a lifetime cancer risk of 10^{-4} or lower is required only if the cost is reasonable; i.e., the risk goal under CERCLA essentially defines an upper bound on negligible risk. Indeed, achieving a lifetime cancer risk of 10^{-4} has not been feasible in cleanup of many radioactively contaminated sites (NCRP, 2004).

Protective action guides for radiological incidents

In cooperation with other federal agencies, EPA (2017) developed guidance to state and local authorities on protective actions to be taken in response to accidents and other incidents in which radionuclides are released to the environment, including accidents at nuclear facilities, transportation accidents, and terrorist acts involving a radiological dispersal device or improvised nuclear device.

Protective action guides (PAGs) are defined for three time phases:

- Early phase: Time from hours to days after an event, when immediate decisions about responses (e.g., sheltering, evacuation, administration of stable iodine) are required;
- Intermediate phase: Time from weeks to months after an accident or incident is brought under control, when the need for additional protective actions (e.g., control of foodstuffs and drinking water, control of access to contaminated areas, relocation of populations) can be assessed based on environmental measurements;
- Recovery phase: Time from months to years, when actions can be taken to reduce levels of radionuclides in the environment and allow permanent residence at a site.

EPA's current PAGs are described in [Table 5](#). Dose criteria generally are consistent with protection standards for workers or the public in other exposure situations.

Table 3 Protection criteria in regulations for specific sources of radiation in the environment established by EPA, NRC, and DOE under authority of Atomic Energy Act.

<i>Regulation</i>	<i>Protection criteria</i>
Operations of uranium fuel-cycle facilities—EPA's 40 CFR 190 (1977)	Annual dose equivalent to whole body (0.25 mSv), thyroid (0.75 mSv), or any other organ (0.25 mSv) Releases of ^{85}Kr , ^{129}I , ^{239}Pu plus other alpha emitters
Management of uranium and thorium mill tailings—EPA's 40 CFR 192 (1983, 1995) ^{a,b}	Emission rate of radon to atmosphere or concentration of radon decay products in air (including background) in occupied or habitable buildings Concentrations of ^{226}Ra plus ^{228}Ra , gross alpha-particle activity excluding radon and uranium, ^{234}U plus ^{238}U in groundwater Concentration of ^{226}Ra in soil above background Gamma radiation level above background in occupied or habitable buildings Individual dose constraints (EPA's 40 CFR 190) Radioactivity in liquid discharges to surface waters (EPA's 40 CFR 440) Standards at uranium processing sites, except standards for radon and decay products, apply to thorium and decay products
Release or clearance of property containing residual radioactive material—DOE Order 458.1 (2011)	Dose constraints for each clearance—annual effective dose for real property (0.25 mSv) or personal property (0.01 mSv) Preapproved authorized limits for release of personal property [annual effective dose (0.01 mSv) and collective effective dose (0.1 person-Sv)] or real property (concentrations of ^{230}Th / ^{226}Ra , ^{232}Th / ^{228}Ra in soil) Authorized limits requiring DOE approval based on applicable dose constraint (radioactivity per unit surface area, mass, or volume)
Decontamination and decommissioning of licensed facilities (except uranium and thorium mill tailings sites)—NRC's 10 CFR 20, Subpart E (1997)	Annual effective dose equivalent to permit unrestricted use of contaminated land and structures (0.25 mSv) or license termination under restricted conditions (0.25, 1, or 5 mSv)
Management and disposal of spent fuel, high-level waste, and transuranic waste, except disposal at Yucca Mountain, Nevada, site—EPA's 40 CFR 191 (1985, 1993) ^{c,d}	Management and storage—Annual dose equivalent to whole body (0.25 mSv) or any organ (0.25 or 0.75 mSv) Disposal—For 10,000 years, (1) cumulative releases of radionuclides to accessible environment, (2) annual effective dose equivalent from releases from undisturbed disposal system (0.15 mSv), and (3) protection of groundwater (EPA's 40 CFR 141)
Management and disposal of spent fuel and high-level waste at Yucca Mountain, Nevada, site—EPA's 40 CFR 197 (2001) ^e	Management and storage—Annual effective dose equivalent (0.15 mSv) Disposal—(1) Annual effective dose equivalent from releases from undisturbed disposal system or inadvertent human intrusion up to 10,000 years (0.15 mSv) and beyond but within period of geologic stability (1 mSv) and (2) protection of groundwater for 10,000 years (EPA's 40 CFR 141)
Near-surface disposal of radioactive waste—NRC's 10 CFR 61 (1982, 1993)	Annual dose equivalent to whole body (0.25 mSv), thyroid (0.75 mSv), or any other organ (0.25 mSv) beyond site boundary Protection of inadvertent intruder—(1) Dose limits in radiation protection standards (10 CFR 20) and (2) concentrations of radionuclides in three classes of waste
Disposal of low-level waste—DOE Manual Chapter M 435.1–1 (1999)	For 1000 years— Annual effective dose equivalent from all release and exposure pathways, excluding radon and decay products (0.25 mSv) Annual effective dose equivalent from releases to air, excluding radon and decay products (0.1 mSv) Average release rate of radon or concentration of radon in air at facility boundary Concentrations of radionuclides based on effective dose equivalents to inadvertent intruder (1 mSv annually for chronic exposure, 5 mSv total for acute exposure)

^aApplicable standards depend on whether site is active or inactive (uranium processing sites only) and whether site is managed by DOE or by NRC or Agreement State licensee.

^bNRC standards for decontamination and decommissioning of licensed thorium mills and uranium recovery facilities in 10 CFR 40, Appendix A (1999), conform in most respects to EPA's 40 CFR 192.

^cStandards presently apply only to disposal of DOE's defense transuranic waste at Waste Isolation Pilot Plant (WIPP) in New Mexico.

^dNRC's licensing criteria for geologic repositories subject to EPA's 40 CFR 191 are established in 10 CFR 60 (1983, 1996). NRC does not license disposal at WIPP.

^eNRC's licensing criteria for disposal at Yucca Mountain site in 10 CFR 63 (2001) include standards in EPA's 40 CFR 197.

Summary and conclusions

The system of radiation protection developed by ICRP and NCRP is the basis for many current standards to control exposures of workers and the public in the U.S. The foundation of this system is the three principles of radiation protection: (1) justification of all exposures (positive net benefit); (2) optimization of protection (maintaining all exposures ALARA); and (3) limitation of dose to individuals in planned (routine) exposure situations.

Table 4 Protection criteria in regulations and guidance for specific sources of radiation in the environment established by EPA under authority of laws other than Atomic Energy Act.

<i>Regulation/applicable law</i>	<i>Protection criteria</i>
Radioactivity in community drinking water systems—40 CFR 141 (1976, 2000) (Safe Drinking Water Act) ^a	Maximum contaminant levels (MCLs) of radionuclides— Concentrations of alpha-emitting radionuclides (²²⁶ Ra plus ²²⁸ Ra, uranium, gross alpha-particle activity excluding radon and uranium) Concentrations of man-made beta/gamma-emitting radionuclides corresponding to annual dose equivalent to whole body or any organ (0.04 mSv), ^b except MCLs for ³ H and ⁹⁰ Sr
Liquid discharges from radium, uranium, or vanadium mines and mills—40 CFR 440 (1982) (Clean Water Act)	Concentrations of dissolved ²²⁶ Ra, total ²²⁶ Ra, uranium in daily effluents and average concentrations in daily effluents for 30 consecutive days
Cleanup of residual radioactive material other than uranium and thorium mill tailings—40 CFR 300 (1990) [Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA)]	Applicable or relevant and appropriate requirements (ARARs) established under other federal and state environmental laws, including EPA's drinking water standards (40 CFR 141) for remediation of groundwater or surface waters Goal for upper bound of lifetime cancer risk from all substances and all exposure pathways combined (10^{-6} to 10^{-4}) ^c
Airborne emissions of radionuclides—40 CFR 61 (1989–1996) (Clean Air Act)	Annual effective dose equivalent from emissions of radon from uranium mines (0.1 mSv) Annual effective dose equivalent from emissions of radionuclides other than radon from DOE facilities other than those subject to EPA's 40 CFR 191 or 192 (0.1 mSv) Annual effective dose equivalent from (1) emissions of radionuclides, including iodine, from facilities other than NRC licensees and DOE sites (0.1 mSv) and (2) emissions of iodine (0.03 mSv) Annual emissions of ²¹⁰ Po from elemental phosphorus plants Emission rate of ²²² Rn from DOE facilities, inactive phosphogypsum stacks, and inactive uranium mill tailings piles except those licensed by NRC Concentration of ²²⁶ Ra in phosphogypsum used in agriculture Radon concentration in air—
Guidance on mitigation of indoor radon in homes and schools (EPA and DHHS, 1994) (Indoor Radon Abatement Act)	Mitigation should be undertaken at $> 150 \text{ Bq m}^{-3}$ (4 pCi L^{-1}) Mitigation should be considered at 70 to 150 Bq m^{-3} ($2 \text{ to } 4 \text{ pCi L}^{-1}$), especially when $< 70 \text{ Bq m}^{-3}$ is achievable

^aDOE Order 458.1 (2011) applies EPA's drinking water standards to releases from DOE sites that may impact public or private drinking water supplies.

^bRadionuclide concentrations corresponding to specified annual dose equivalent to whole body or any organ are calculated assuming daily consumption of drinking water of 2 L and committed dose equivalents per unit activity intake from NCRP Report No. 22 (NCRP, 1959), as amended in 1963.

^cEPA considers that goal of 10^{-4} is met at radioactively contaminated sites if annual effective dose equivalent does not exceed 0.15 mSv.

Table 5 Guidance on protective actions in response to radiation accidents and incidents developed by EPA and other federal agencies (EPA, 2017).

<i>Time phase</i>	<i>Protective action</i>	<i>Protective action guide (PAG)</i>
Early	Sheltering in place or evacuation of population	Projected effective dose over 4 days > 10 to 50 mSv
	Supplemental administration of potassium iodide (KI)	Projected equivalent dose to child's thyroid from exposure to radioactive iodine > 50 mSv
Intermediate	Limit exposure of emergency workers over entire response	Annual effective dose < 50 mSv; higher limit may apply under exceptional circumstances
	Relocation of population	Projected effective dose in first year > 20 mSv Projected effective dose in second and subsequent years > 5 mSv
	Apply simple dose reduction techniques	Projected effective dose in first year > 20 mSv
	Control of food supplies	Projected annual equivalent dose > 5 mSv to whole body or > 50 mSv to any organ
	Control of drinking water supplies	Projected effective dose in one year > 1 mSv to most sensitive populations (e.g., infants, children, pregnant and nursing women) or > 5 mSv to general population
Late ^a	Limit exposure of emergency workers over entire response	Annual effective dose < 50 mSv
	Reentry for access to relocation zone	Effective dose in 1 year < 5 mSv for temporary access
	Cleanup	Description of planning process
	Waste disposal	Description of planning process

^aIn previous guidance, EPA (1992) recommended that annual effective dose equivalent to the public after the first year should not exceed 5 mSv and total effective dose equivalent over 50 years, including first and second years, should not exceed 50 mSv (annual average of 1 mSv). For reactor accidents, EPA expected that objectives would be met if PAG for intermediate phase of 20 mSv in first year is met.

Standards to control radiation exposures of workers and the public have two basic objectives: (1) limitation of the risk (probability) of stochastic effects, principally solid cancers and leukemias, and (2) prevention of tissue reactions (nonstochastic effects) in all organs and tissues. In planned exposure situations, tissue reactions usually are prevented by complying with limits on effective dose equivalent or effective dose to individuals, which are intended to limit risks of stochastic effects. This is especially the case in planned exposures of the public.

As radiation protection practices evolved over many decades, application of the ALARA principle became the most important means of controlling exposures of workers and the public in any situation. For example, the average annual dose to workers at nuclear power plants typically is only a few percent of the limit of 50 mSv in NRC regulations, and the highest annual doses to the public due to releases of radionuclides in normal operations of nuclear power plants typically are < 1% of EPA standards in 40 CFR 190. Consequently, in normal operations of nuclear power plants, dose limits for workers and the public are largely irrelevant. More generally, most radiation exposures of workers and the public are controlled by use of dose constraints in planned exposure situations at a fraction of an applicable dose limit and other protection criteria in environmental standards for specific sources, which represent exposure conditions judged to be reasonably achievable, and further application of the ALARA principle.

Introduction

By now, readers of this section on radiation protection will know that ionizing radiation presents a human health risk, that the risk associated with most radiation exposures is cancer incidence, and that the chance of developing a radiation-induced cancer increases with increasing dose. If one presumes that any amount of radiation exposure, no matter how small, is associated with an increased chance of cancer, then the relationship between dose and cancer risk is described as conforming to a linear no-threshold (LNT) model.

If the LNT model is all one understands about radiation, or all one considers when establishing regulations or controls, then the approach for mitigating risk seems straightforward—prevent or prohibit any radiation exposure and then all excess cancers will be avoided. To a large extent, this is a simple and practicable protective approach, and maintaining exposures as low as reasonably achievable, or ALARA, is an important principle that guides virtually every radiation protection program in the world.

In the United States, federal policymaking requiring elements of ALARA can be traced back to at least 1970 when the predominant nuclear regulatory agency at the time, the Atomic Energy Commission, added an “as low as practical” provision to its regulations rather than publish absolute dose limits. The Energy Reorganization Act of 1974 marked the end of the Atomic Energy Commission and transferred certain regulatory functions to a new agency, the Nuclear Regulatory Commission (NRC), and in 1975, the NRC changed the terminology from “as low as practical” to “ALARA”. The ALARA requirement remains in effect today and obliges radioactive material licensees under NRC and Agreement State jurisdictions to demonstrate efforts to minimize both individual and collective doses to the lowest extent achievable.

The underlying promise of an ALARA-based program is that regardless of how low the current dose, reasonable efforts to make the dose even lower are valuable. The reward seems clear, as according to the linearity predicted by an LNT model, a reduction in dose translates directly to fewer cancers. As a result, considerable extra effort is often expended on actions to further reduce doses that are already below regulatory limits because such efforts are expected to improve health.

In terms of net health outcomes, however, there is not any direct evidence that the nation’s five-decade commitment to ALARA has benefited the public. Studies examining health outcomes in nuclear workers, in persons who reside near nuclear power stations, and in other regularly exposed cohorts do not produce results showing the linearity predicted by the LNT model. Conversely, there is ample evidence to suggest that policy actions such as ALARA that are singularly focused at reducing one risk often lead to important risk tradeoffs that create or exacerbate other health risks.

Take for example a worker who is routinely exposed to small amount of airborne radioactivity within regulatory limits for such an exposure. If one is interested in reducing the probability that the worker develops a radiation-induced cancer according to ALARA, additional controls should be taken to further reduce the worker’s dose if deemed reasonably achievable. A simple yet effective intervention where airborne radioactivity is concerned is to require the worker to wear respiratory protective equipment. Because the respirator prevents radioactivity from entering the body to a large extent, the worker dose and presumed risk of radiation-induced cancer incidence are reduced. However, wearing a respirator limits a person’s field of vision and makes breathing more difficult, and these and other factors resulting from respirator use introduce new health risks. The relative magnitude and potential severity of the new risks should be evaluated to determine the net impact of the intervention on the worker’s health. If the new risks outweigh the perceived benefits, the value of the intervention should be reconsidered.

As the previous example demonstrates, it is not always reasonable to make doses lower. However, without criteria explaining what is reasonable, practitioners who are reluctant to be found operating at odds with regulations that require ALARA will often take actions to make doses as low as possible. “As low as possible” does not have nearly the same meaning as ALARA. If we are truly interested in lowering doses as a means of protecting the public and improving health, then we should be as equally concerned with negative outcomes of such interventions.

The purpose of this article is not to criticize the practice of ALARA. Rather, it examines certain factors that should be understood whenever dose-limiting actions are planned to determine if such actions are reasonable. These factors include a factual understanding of radiation effects in humans, risk tradeoff, and moral disengagement theory.

Perceived versus actual effects of radiation

Ionizing radiation was discovered in 1895, and it was initially studied and used without any concerns or controls (Walker, 2000). Researchers often experimented on themselves and others in a manner leading to severe overexposures, and the degrading health of scientists and their subjects in the first few decades following radiation's discovery left little doubt that it was harmful. By the early 20th century, the public understood that large exposures presented a health hazard; nonetheless, work and research with radiation continued without a tremendous amount of public outcry.

Public perceptions changed in 1945 when the United States detonated two nuclear weapons over the Japanese cities of Hiroshima and Nagasaki. Although it is not known which deaths were due to radiation and which were due to the blast or heat, about 39% of the population of Hiroshima and 28% of the population of Nagasaki were killed (Nagataki, 2010). About half of the deaths occurred in the period spanning 20–29 days after the bombings, and nausea, vomiting, diarrhea, purpura, epilation, and other symptoms of acute radiation syndrome (i.e., radiation sickness) were observed within a few days to several weeks after the bombing (Nagataki, 2010). The shocking images returned from the aftermath and reported by the media generated considerable public concern about the harmful effects of radiation, and to a large extent, that concern persists to the present day.

Shortly after the bombings, radioactive fallout could be detected on the California coast which further exacerbated public concerns in the United States. These concerns resonated in a California town with an appetite for what interests the public, Hollywood, and blockbuster after blockbuster promising nuclear apocalypse soon followed. The effects of radiation were overwhelmingly embellished in such films, and audiences left theaters contemplating to what extent radiation could mutate insects and other creatures into monsters or cause other horrific abominations.

Fortunately, the range of possible radiation-induced biological effects differs greatly from the Hollywood exaggerations that continue to entertain the public. When such effects are described by researchers and practitioners, a popular way to categorize them is whether they are “early” (often called “acute”) or “late” (sometimes called “delayed”). When this manner of categorization is used, the category names refer to the length of time for the biological effect to manifest. Acute effects are usually observed in the days, weeks, or months following an exposure; whereas late effects may not be seen for years or decades.

Evidence that high levels of radiation present acute effects is observed in studies of atomic bomb survivors and nuclear accidents (NAS, 2006). The acute effects demonstrated in bomb survivors have already been described, namely, radiation sickness and death. The effects have been confirmed in other studies involving large acute exposures. For instance, 134 people demonstrated symptoms of acute radiation syndrome following the Chernobyl nuclear accident, and 28 died within 3 months (Nagataki, 2010). Although these are grave effects, it is important for readers to understand that the exposures leading to acute effects must be unusually large and received over a short period of time.

In addition to acute effects, late effects are also observed in A-bomb survivors. Although other late effects are possible, a 50% excess solid-cancer risk is estimated in survivors exposed to 1 Sv (Nagataki, 2010; NAS, 2006). A solid cancer is characterized by an abnormal growth of cells that leads to a solid “mass” or “tumor”, as opposed to liquid cancers such as lymphomas and leukemias that are present in body fluids. A sievert, or Sv, is a unit of biologically weighted absorbed dose that is equivalent to depositing 1 joule of energy per kilogram of tissue. This definition of a Sv is not particularly meaningful except to radiation professionals, so it is helpful to think about it as a unit of dose that may be translated to risk.

Because an understanding of radiation-induced cancer risk is so important to the current discussion, the risk-magnitude inferred by the sentence introducing the preceding paragraph will be reviewed. First, a whole-body dose of 1 Sv will not be obtained except in unique circumstances such as nuclear catastrophes. For example, if a standard chest X-ray procedure is presumed to give a dose of 0.0001 Sv, then 1 Sv is approximately the dose a person would receive if exposed to 10,000 chest X-rays. A 50% excess risk corresponds to a relative risk of 1.5, meaning a person exposed to this large dose would still only be 1.5 times as likely to develop a solid cancer as a person not exposed. This does not mean a person would die from the cancer, only that the probability of developing a cancer at some point in that person's lifetime is increased. Finally, radiation-induced cancer is not different from other cancers. For example, it is impossible to distinguish which brain cancers in A-bomb survivors are due to radiation and which are due to other factors.

In A-bomb survivors, higher and lower cancer risk is associated with exposures above and below 1 Sv, respectively, and the dose-response relationship appears to be linear down to 0.1 Sv (NAS, 2006). Research involving late effects in other cohorts, however, do not necessarily conform to predictions using data from atomic bomb survivors. Nonetheless, solid cancer (i.e., cancers other than leukemia and other hematopoietic cancers) is usually discussed in terms of being the most important late effect.

Below a dose of about 0.1 Sv, or approximately equal to what would be received from 1000 chest X-rays, the actual risk remains unknown. This is true despite examining health outcomes in hundreds of thousands of diverse human subjects over the better part of a century. Researches have studied late effects in A-bomb survivors; persons receiving medical radiation; nuclear industry workers; airline and aerospace employees; cleanup workers; doctors and dentists; people living near nuclear facilities; populations exposed to the Chernobyl accident, environmental releases of radiation, fallout, and natural background radiation; children of adults exposed to radiation; and other exposed cohorts (NAS, 2006; GAO, 2000). Thus, the fact that the risk remains unknown is not because

scientists lack data, but because so few (or any) excess cancers and other late effects are observed below 0.1 Sv that the risk is too low to determine. If we categorize doses above and below 0.1 Sv as “high” and “low” doses, respectively, then we simply do not have any statistical evidence of late effects for low doses unless we presume it is reasonable that the relationship for high doses applies to both dose ranges.

The fact that low doses of radiation presents little if any risk is evidenced by the everyday exposures that the public tolerates. Air travelers receive a higher dose of cosmic radiation than persons who travel by car because less cosmic radiation is shielded by the atmosphere. Living at a higher altitude has a similar effect, thus residents of Denver receive more dose than persons living near sea-level. A large number of medical and dental diagnostic procedures rely on radiation that patients accept. People choose professions that result in a bit more dose than the general public will receive, such as nuclear power plant workers, X-ray technicians, and pilots and flight attendants. If these exposures were regularly resulting in excess cancers, the public would be inclined to avoid them.

The takeaway from this concise primer on biological effects is that ionizing radiation is considerably less hazardous than the public perceives it to be. In the end, we find that the most likely effect is an increased probability of developing cancer, but even then it takes a large amount of radiation exposure to a large population to see a measurable increase in cases as low-dose radiation is not a very efficient cancer-causing agent.

Risk tradeoff and analysis

If low-dose radiation is understood to present little hazard, one might ask why it is regulated at all. Shortly after the NRC was established, the agency did contemplate whether very low levels of radiation exposure could be designated as “below regulatory concern” (BRC). Such levels of exposure were stated to be associated with public health risks so small or nonexistent that there did not appear to be value in expending regulatory resources. After more than a decade of debate, the NRC issued a policy statement in June 1990 declaring certain low levels of radiation BRC (Walker, 2000). The resulting public outcry was so enormous that Congress initiated legislation to block BRC, and 12 states and more than 100 local governments eventually took steps to prohibit implementation of the policy (Walker, 2000). Due to the overwhelming public and political response, the NRC declared a moratorium on implementation of the policy, and the moratorium was indefinitely extended in December of 1991 (Walker, 2000).

In part, what the NRC was trying to accomplish with its policy on BRC was to improve public health by preventing overregulation. Interventions, such as policies, regulations, and other actions aimed at mitigating a risk, are understood to often exacerbate or create other health risks (Graham and Wiener, 1995). The risk that is addressed by the intervention is called the target risk, and the risks that arise or are increased are called countervailing risks. The process wherein a target risk reduction is traded for countervailing risk is called risk tradeoff (Graham and Wiener, 1995). Where overregulation happens, risk tradeoff occurs without the benefit of a tangible reduction in the target risk, and the net result is overall poorer health outcomes than what are possible if the target risk were optimally regulated.

The fact that risk tradeoffs do occur is evidenced in contemporary research that examines the net benefit of radiation policymaking. For example, more than 1900 unnecessary deaths are attributed to mandatory evacuations that followed the 2011 disaster at the Fukushima Daiichi nuclear power plant (Hayakawa, 2016). The evacuations were conducted to avoid the same amount of radiation and risk one might receive from a common medical procedure, a dose of about 0.02–0.1 Sv, but the physical and mental stresses associated with evacuee living have caused considerable harm including death (Hayakawa, 2016). In another example, a 2004 study conducted by the US Department of Energy concluded that the agency had spent more than \$60 billion since 1989 on radioactive site cleanup without realizing a reduction in actual health risk because the work introduced a number of ecological, temporal, and human health tradeoffs (Burger et al., 2004).

Sources of risk tradeoff

The likelihood of risk tradeoff occurring increases when decision-making is conflicted by certain concerns that are deemed “sources” of risk tradeoff (Graham and Wiener, 1995). The first of these sources is called “bounded roles” and reflects the biases that arise when regulatory agencies are structurally separated into groups of specialists. Specialists assigned to radiation protection agencies or departments who are tasked with reducing radiation-induced cancers will naturally accept risk tradeoffs to achieve such reductions. Moreover, experts on radiation effects may possess little knowledge of risks or hazards outside their specialty. “Omitted voice” is a source of risk tradeoff when the voices of some impacted parties are heard but others are not, as decision makers are likely to consider what is heard as reflecting the desires of the majority when that might not be the case. “Heuristics” are cognitive tools that have evolved in humans over generations. These tools allow large amounts of data to be quickly sorted for use in decision-making, but they do not work flawlessly. Heuristics are responsible for a tendency to focus on recent events or what are perceived as immediate concerns and to ignore the consequences of one’s responding actions until they become issues later. People are reluctant to accept change, making “old technology bias” a source of risk tradeoff whenever something new or innovative is attempted, and “human behavioral responses” are sources of risk tradeoff when actions taken to reduce risk unintentionally lead to other risky behaviors.

When decision-making is impacted by one or more of the preceding source concerns, the benefits and harms of the outcome decisions affecting risk should be analyzed. Federal agencies have been required to accomplish some means of benefit-cost analysis in conjunction with their regulatory actions since 1981 when then President Ronald Reagan issued Executive Order 122291 (NRC,

2017). Presidents Bill Clinton, George W. Bush, and Barack Obama have signed similar Orders requiring agencies to select interventions that maximize net benefits when economic, environmental, public health and safety, equity, and other factors are considered. Notwithstanding such Orders, NRC maintains that as an independent agency, it is not statutorily required to conduct comprehensive regulatory analysis (NRC, 2017). Instead, it relies on an analysis tool called probabilistic risk assessment, or PRA, that exclusively examines the monetized population dose that is averted and other economic costs of a decision.

All of the possible sources of risk tradeoff are present when ALARA is practiced to limit dose. The practice itself is handed down in regulations borne from specialists in agencies with bounded roles. These specialists are likely to hear from entities interested in radiation's risks and not from voices interested in other risks. The term ALARA is meant to appeal to our heuristic nature as it seems reasonable to keep doses as low as possible, and ALARA has been practiced in some form or fashion since the onset of environmentalism, making it subject to old technology biases. Over the years, human behavioral responses are responsible for ALARA being practiced in a manner aimed at achieving lower and lower doses, even when such practices are known to exacerbate other risks. There is little doubt that ALARA-based interventions lead to risk tradeoffs, yet few of these interventions are analyzed in terms of their net benefit to society.

Risk tradeoff analysis

Risk tradeoff analysis, or RTA, is a comparative risk assessment technique that seeks to identify risk tradeoffs, weigh the comparative importance of target and countervailing risks, and explore opportunities to reduce risk (Graham and Wiener, 1995). Because it is concerned with optimizing health outcomes rather than the financial costs borne by taxpayers, regulated industry, and consumers, RTA is particularly valuable for evaluating the reasonableness of interventions where there is a reluctance to make tradeoffs between monetary costs and health (Graham and Wiener, 1995). As a mechanism for eliminating policy alternatives that are clearly not to society's benefit, RTA is superior to other popular frameworks for comparative risk assessment that rely heavily on cost-effectiveness, such as benefit-cost analysis (Hofstetter et al., 2002).

RTA is practiced by first identifying the goal of the risk-reducing intervention. To "maintain exposures ALARA" is not an explicit enough goal—the target risk and target population must be stated. Where radiation dose limitations are concerned, the target risk is almost exclusively cancer. Target populations are typically workers, members of the public, or both. Radiation protections are sometimes planned to protect hypothetical populations, and the distinction of whether the population is real or theoretical is important to RTA. For example, moving the fence at the boundary of a nuclear facility outward 10 meters could be planned to reduce dose and thus cancer risk to a person who builds and resides in a home just outside the boundary. If no one presently lives at the boundary and it is unknown (or unlikely) that anyone ever will, the protection is based on reducing risk to a theoretical receptor. Workers would be needed to implement the intervention, and these real persons would be subject to risks such as occupational injuries while lifting and moving the fence.

The next step in RTA is to identify any countervailing risk(s). This is not a task that should be taken lightly, because for RTA to be effective, the list of countervailing risks must be thorough. As an example, consider that the NRC applies a dose limit of 0.25 mSv to cleanup of former nuclear sites and that several states use lower limits. It would be easy to conclude that the countervailing risks presented by the states' levels are a bit of extra cleanup and cost, and that these risks do not outweigh the benefits of the dose reduction. A substantive look at the extra cleanup work, however, reveals that it is done by workers who are subject to risk from occupational injuries and illness. Cleanup work often involves degraded structures, heavy equipment and tool use, cranes and rigging, and a variety of other ergonomic and environmental hazards. Wastes that are generated during cleanup are transported for disposal, and extra waste means extra vehicles in transport and an increased risk of traffic accidents. Heavy equipment and the vehicles used to transport waste burn fossil fuels, and their exhausts contribute to health risks from air pollution. If the cleanup is conducted outside, ecosystem disruptions and resulting risks must be considered. Because risks can lead to negative or positive outcomes, a positive outcome that must also be considered is that workers benefit from the extra wages and health insurance they are afforded if the job last longer. All these risks aside, extra cleanup rarely if ever returns the benefit it promises, fewer radiation-induced cancers, because (1) the models used to design cleanup are almost always based on doses to worst-case theoretical receptors rather than to real people and (2) excess cancer incidence is already insignificant or nonexistent at a level of 0.25 Sv.

Once countervailing risks are identified, each is examined in terms of its typology. According to RTA, there are four qualitatively different types of risk tradeoffs: risk offset, risk transfer, risk substitution, and risk transformation (Graham and Wiener, 1995). The typology is determined by deciding if the countervailing risk is the same or different than the target risk and if it impacts the same or different population.

A "risk offset" occurs when the target risk and the countervailing risk are the same and affect the same population. In the case of radiation protection efforts, this would mean that a dose-limiting intervention is expected to cause a certain number of cancers in the same population (e.g., workers) that it was expected to benefit. Any cancer-risk increases offset anticipated reductions. Intrinsically, risk offsets are easier to analyze than other types of risk tradeoffs because the comparisons are said to be "apples to apples". Note the importance of understanding the reality of the impacted population, as preventing five cancers in theoretical workers is not the same as causing five cancers in the actual workforce.

"Risk transfer" happens when the target risk is transferred from one group to another. The risk is the same, so for dose-limiting controls this means cancer risk is reduced in one group and transferred to another. The circumstances surrounding extra cleanup to reduce public dose lead to risk transfer because workers receive extra dose to accomplish such cleanup. Thus, radiation-induced cancer risk is transferred from the public to workers.

Actions taken to prevent cancer through dose reduction can lead to other risks. A “risk substitution” occurs if the population benefiting from the target risk reduction experiences a different risk, and a “risk transformation” occurs when a new group is affected by a different risk than the intervention was meant to address. A worker whose dose is limited by a respirator is subject to risk substitutions from occupational injuries that the respirator could cause, and a public that benefits from cleanup experiences a risk transformation when the vehicles used to transport wastes degrade traffic conditions and air quality.

While knowing the typology of risk tradeoff is important, the true value of RTA is not realized until the benefit and detriment of a proposed intervention are compared in a meaningful manner. This is accomplished by weighing the risks according to magnitude of risk, size of population impacted, certainty of risk estimates, type of adverse outcome, distribution, and timing (Graham and Wiener, 1995).

The magnitude of a risk refers to its probability. Magnitude is a particularly useful comparison tool when the outcomes from the target and countervailing risks are identical, for example fatal cancer versus fatal cancer. A compelling advantage of probability comparisons is that successful decisions are evaluated based on their ability to achieve risk-superior outcomes rather than their ability to drive a target risk down to some arbitrary threshold that may not be significant.

Considering the size of the population exposed to the risk is important in order to avoid transferring risks onto larger populations. For example, if both the target and countervailing risks are 1 in 100,000 chance of lifetime attributable cancer risk, and 100,000 persons are exposed to the target risk whereas 1,000,000 people are exposed to the countervailing risk, a dose-limiting action resolving 1 target cancer could result in 10 unintended cancers.

Certainty of risk estimates is important as some outcomes are consistently and concisely defined while others are speculated or assumed. RTA acknowledges that the degree of scientific uncertainty may differ and recommends quantifying uncertainty with classical statistics when possible. When circumstances cannot be translated objectively it may be necessary to introduce technical judgments from experts. Symmetrical reporting is needed for certainty comparisons. For example, if worst-case estimates are reported for target risk, the same type of estimates should be reported for countervailing risks, otherwise, comparisons are not possible.

Comparing the types of adverse outcomes is possible when risks can be viewed in meaningful, common ways, but such comparisons are often complicated by a lack of precision. They normally involve value judgments rather than objective comparisons along a unidimensional scale. For example, can equal probabilities of death by cancer and death by heart disease be characterized as equivalent outcomes? Is death by cancer worse than living with decades of permanent disability or pain? These are the kinds of value judgments that must be made and qualified when comparing different types of adverse outcomes. Nonetheless, research does demonstrate that humans possess the ability to quantify their dislike for certain equally probable outcomes, and it is possible that as risk analysis measures mature, meaningful comparisons of different outcomes may be possible. A key qualitative difference that is valuable for comparisons is that some risks are felt to be controlled by the individual and voluntarily, while others seem outside of one’s control and involuntary. Risks that arouse fear and risks that explicitly affect children and disadvantaged members of society are also qualitatively different from other risks.

Distributional considerations assess how the risk is shared. Who incurs the risks, are they equally distributed among the population, and is one or more groups disproportionately affected? These and other ethical societal matters are examined when comparing target and countervailing risks along distributional factors. From a distributional viewpoint, risks are generally more tolerable when every person has an equal chance of experiencing the adverse outcome, regardless of any discernable characteristics such as race, age, or socioeconomic status. Political pressures may incentivize governments to trade risk from one group to another; thus, distributional considerations are particularly important when the countervailing risk impacts underrepresented human and nonhuman populations.

Timing of risks is concerned with the ethics of which group should bear the risks and when. This factor considers the time it takes the risk to pose an imminent threat to health. An outcome that presents after a protracted latency may be perceived as a smaller risk than an imminent one; for example, cancer may not express itself for years or decades, whereas trauma is proximately distressing. Timing also considers whether the risks impact current or future generations.

Recognizing and identifying the risk tradeoffs due to dose-limiting actions can be challenging, and the effort is complicated by ethical concerns. RTA cannot be accomplished exclusively with empirical means. Rather, these analyses are informed by a combination of objective information and personal judgment. In some instances, countervailing risks will be determined to exhibit inconsequential or tolerable risks, and in others, the countervailing risk may rival or outweigh the benefits expected from reducing dose. Equipped with knowledge of countervailing risks, a decision-maker is faced with weighing risk versus risk in a manner that best serves the public, with appropriate consideration given to the analysis of experts and what is ethical. In the end, it is hoped that decision makers find opportunities to resolve tradeoffs with risk superior mitigating actions, materials, and technologies. In some instances, this may mean accepting the risk reflected by a low dose of radiation and that further actions to reduce dose are not reasonable.

Moral disengagement theory

If the actual biological effects of low-dose radiation are known to be largely insignificant, and the phenomenon of risk tradeoff and its sources are similarly well understood, then it seems almost inconceivable that radiological control policies and practices would be designed in a manner resulting in other than optimal health outcomes. One would be naive to believe that decision-making practices, particularly decisions leading to policymaking, are based entirely on a factual understanding of risk. That is, while

knowledge certainly contributes to decision making, other important factors such as beliefs, feelings, and perceptions of how others will judge decisions are just as important—or more so—when it comes to decision outcomes. In the end, decision making is a behavior, and like other behaviors, it is influenced by a variety of social-cognitive elements and is happening at a level of consciousness that is not always concerned with factual evidence. Such influences are described and investigated with behavioral models and theories.

Of the tools available for analyzing social behavior related to public health decision making, Bandura's theory of moral disengagement is a popular technique for examining behaviors that lead to detrimental outcomes. The theory seems somewhat misnamed, as it does not stem from a belief that people are bad actors. Rather, the underlying assumption of the theory is that people have an innate desire to make decisions and to otherwise act according to an intrinsic moral code (Bandura, 2002). Because people know right from wrong and are interested in acting in a moral manner, their behavior is expressed via self-regulated processes that prevent violating personally-held moral standards (Bandura, 2002).

When one's actions are contrary to that code, a variety of similarly embedded cognitive tricks are used to justify the behavior. Such tricks allow behaviors leading to detriment to be interpreted as not at odds with one's moral character, including behaviors that could be deemed reprehensible such as cruelty and various forms of physical, social, and cognitive harm to others. We see evidence of moral disengagement in countless everyday situations: a person may overwhelm their children with gifts for the holidays but ignore people next-door who are hungry, a responsible health and safety manager may operate their own automobile at speeds above posted limits or cross the street without waiting for a crosswalk signal, a radiation safety professional may subject workers and the public to unnecessary non-radiological hazards to protect against low-dose radiation. When these behaviors are exhibited by people who seem fundamentally moral, there must be elements underlying the decision-making leading to such outcomes that can be examined and explained.

Moral disengagement theory is characterized by nine constructs that reflect justifying behaviors (Bandura, 2002). "Moral justification" refers to the tendency to consider oneself acting as a social or moral agent and in a way benefiting society. With moral justification, otherwise harmful conduct is accepted because it serves a moral purpose. Via "palliative comparison", harmful conduct is deemed a righteous retaliatory behavior against the outcome it is meant to contradict, prevent, or eliminate. The moral response to harmful conduct can be softened with language skills such as "euphemistic labeling" wherein humans and outcomes are described with sanitizing language such as "targets" and "collateral damage". Euphemistical labeling can also be used to make reprehensible conduct seem to be the work of nameless forces rather than people. A person may minimize their role as an agent in the harm that is caused with "displacement of responsibility", particularly if the decision or action can be attributed to a group. This tactic is used even when the harm comes from a group to which they belong or to claim that they are not responsible for the harm because they were not the one who authorized it. Similarly, "diffusion of responsibility" refers to the justifying behavior through which personal agency is softened by attributing responsibility to other actors as group decision-making provides an opportunity to shirk individual responsibility and blame immoral behavior on others. "Minimizing, ignoring, or misconstruing the consequences" is used to minimize, disregard, or distort the impact of one's actions, "dehumanization" is used to strip away human qualities from people, and "attribution of blame" allows people to view themselves as victims. Self-exoneration is realized in such instances because the harmful conduct is viewed as insignificant, as an act against groups that have not earned our concern, or as a protective response rather than a personal decision that would require moral control. Finally, people are not instantly transformed into cruel actors, and "transformative power of progressive moral disengagement" is the construct by which mildly harmful behaviors become tolerable and slowly progress to more harmful ones.

Just as each of the sources of risk tradeoff is reflected in ALARA practice, actions to limit dose are unmistakably complicated by each of moral disengagement theory's constructs. Because the public perceives radiation to pose such a terrible hazard, moral justification of actions to further limit dose is possible even when such hazards cause other harms. Cancer is considered a terrible outcome, so by palliative comparison, any actions against cancer are moral. The term ALARA was introduced into policymaking as a euphemism to soften the public response to prescriptive dose limits. Displacement and diffusion of responsibility are possible because radiation protection professionals are limiting doses because the rulemaking comes from others and because their department expects them to follow such rules. Radiation protections are known to create other hazards, but these hazards may be ignored or minimized. Regulations provide "occupational dose limits" and "dose limits for individual members of the public" and by separating and dehumanizing workers in this manner it becomes easier to conclude that the public deserves lower limits. Persons living near nuclear facilities may see themselves as victims and blame the operator if they become ill. ALARA will be implemented in an increasingly conservative manner over time as practitioners are praised or rewarded for their efforts, even when they know such efforts may be creating other risks, which demonstrates the transformative power of moral disengagement.

The practice of moral disengagement theory's compensating behaviors occurs instinctively and subtly as a matter of the human cognitive process that has developed over the course of evolution. That is, such behaviors are not constrained to only those persons who are intrinsically cruel. To maximally prevent risk tradeoffs, even the most experienced, knowledgeable, and well-intentioned regulators and practitioners should examine their radiation-protection decision making for evidence of influences leading to moral disengagement.

Conclusion

This article is not an exhaustive examination of the factors leading to risk tradeoff where radiation protections are concerned. Rather, it provides an introductory examination of underlying social, cognitive, and behavioral phenomena that influence decisions related to dose-limiting interventions.

Contrary to public perceptions, low-dose radiation presents little if any risk. Nonetheless, limiting doses with conservative measures such as ALARA pleases the public and provides assurance that excess radiation-induced biological effects are being maximally prevented. If these measures are practiced in a manner that prioritizes radiation protections over other health considerations, however, then such measures are expected to result in risk tradeoffs and possibly harms.

Except in instances where the dose reduction is achieved relatively easily, efforts to make low doses even lower may not be reasonable according to ALARA. That is, as soon as risk tradeoffs become obvious, the intervention is probably not benefiting the public. Regulatory dose limits are already substantively protective, and there is not any evidence of health improvements below these levels. Even the longest-tenured radiation protection professionals will not be convinced that practicing ALARA results in fewer cancers than would be observed by adhering to prescriptive dose limits. Conversely, excess radiation protections are known to contribute to worker injuries, ruin ecosystems, and result in transportation and disposal of vast amounts of relatively innocuous waste. These adverse outcomes are prevented by adhering to prescriptive dose limits without further lowering exposures because of pressure to demonstrate ALARA.

The challenge of making risk informed decisions that consider tradeoffs is that to do so means remaking the paradigm for radiation policy. Omitted voice, heuristics, bounded roles, old technology bias, human behavioral responses, and moral disengagement are pervasive features of the status quo, and it is hard to imagine radiation policymaking occurring without such complications. These complications reflect a systematic failure to see the “whole patient”, where the term “patient” implies the person, population, ecosystem, or combination thereof treated with the intervention. In part, what is needed to remake the policymaking paradigm is to better educate the public on the harmful effects of radiation and the consequences of overregulation. Only by teaming with the public are radiation protection professionals likely to realize optimal public health policy making that takes a whole patient approach where environmental hazards and risk prevention are concerned.

Introduction

When determining acceptable levels of residual levels of contamination in the environment, the question “How clean is clean?” while easy to ask, can be difficult to answer. We live in radioactive world where the food we eat, air we breath, water we drink and the ground we live on contains naturally occurring radioactive materials. This is compounded by the fact that radionuclides that emit ionizing radiation are carcinogens, yet at noted above some of these carcinogens occur naturally in our world. For example, potassium is a vital mineral in our diet however, 0.012% of all naturally occurring potassium contains radioactive potassium-40 (^{40}K). ^{40}K decays by emitting a beta particle (ionizing radiation) yet this radionuclide/carcinogen is present naturally in our environment and can be found in the heart healthy fruit, bananas. A potassium-rich diet can help lower blood pressure and people who eat plenty of potassium have a 27% lower risk of heart disease. So if we were to completely remove potassium from our daily lives because of the small amount of ^{40}K there would be an overall health detriment to the population. Therefore, we balance the minute risk of cancer associated with ingesting small amounts of ^{40}K to overall positive benefits of consuming potassium as a whole.

Obviously not all radioactive elements provide health benefits such as potassium, however, we often approach risk assessments in the same manner. Does the health risk of one action provide a benefit/detriment compared to the health risk of another action? As an example, lets say a site is contaminated with a carcinogen, in this example it does not matter if it is radioactive material or not. Obviously, if the cancer risk was such that there was a 100% chance a person would develop cancer while living on the site, there would be no argument that cleanup would be required. So cleanup to what level? The degree to which we must remediate the site goes back to our original question; “How clean is clean?” Our first instinct may be; “Let’s lets clean to zero.” However, that may be cost prohibitive and what is “zero”? Is “zero” our detection limit? What if new technology is developed and a new detector can now measure the carcinogen at a 100-times lower level than older model that was available during remediation activities? Does that mean the site would have undergo remediation yet again? Or, is there an “acceptable” cancer risk, we as a society are willing to accept such as; 1: 10,000, 1:100,000, 1:1 million, 1:10 million, 1:100 million?

In addition, are there competing risks, associated with remediation activities? For example, if we have to remove 1000 times more soil to go from 1:1million risk to 1:5 million risk, that means there are likely going to be additional shipments of soil from the site, which could lead to more fatal transportation accidents associated with these additional shipments, In addition there are risks associated with added exhaust emissions from the heavy equipment operations and offsite transportation activities of the excavated material. At what point do the remediation activities ultimately increase the fatal risk when compared to leaving the carcinogen in place at an “acceptable” level?

The establishment of an “acceptable” dose or risk level is beyond the scope of this chapter. This chapter will focus on the methodologies used to estimate acceptable residual concentration levels *given* the established dose or risk constraints. This chapter will describe the overall methodology used to estimate residual levels of contamination and review common computer programs available to estimate these residual concentration levels.

Radiation dose limits for remediation activities

Given that there is an established radiation dose or risk level involving remediation/decommissioning activities of a contaminated site, how does one implement these dose or risk constraints. For example, in the U.S. Code of Federal Regulation, 10 CFR 20 Subpart E states (NRC, 2018):

A site will be considered acceptable for unrestricted use if the residual radioactivity that is distinguishable from background radiation results in a TEDE to an average member of the critical group that does not exceed 25 mrem (0.25 mSv) per year, including that from groundwater sources of drinking water, and the residual radioactivity has been reduced to levels that are as low as reasonably achievable (ALARA).

In addition 10 CFR 20 Subpart E states: (NRC, 2018).

When calculating TEDE to the average member of the critical group the licensee shall determine the peak annual TEDE dose expected within the first 1000 years after decommissioning.

Therefore, in addition to complying with a dose-level at the time of decommissioning it is required, in the case of 10 CFR 20, that this dose-level must be met 1000 years after license termination. It should be further noted that in this case 10 CFR 20 is specific in that it states a "TEDE," which is the Total Effective Dose Equivalent. The TEDE is the dose from external radionuclides plus the "50 year committed effective dose equivalent." The 50 year committed effective dose equivalent is the dose accumulated by the body over 50 years given a single uptake of a radionuclide. For accountability purposes the accumulated dose is "delivered" within a year, even though the actual delivered dose over that time period may be far less.

Consider the notional example: The TEDE for radionuclide ^{123}A is 0.2 mSv. However, the dose may be delivered such that 0.1 mSv is delivered in the first year, 0.05 mSv is derived in the 2nd year, 0.03 mSv is delivered in the 3rd year and 0.01 mSv is delivered in the 4th year and the remainder (0.01 mSv) is delivered over the 5th year. Even though the 0.1 mSv was actually delivered to the person in the first year, the TEDE would be 0.2 mSv in this example.

Since the dose-requirement is in the form of a TEDE, or in the case for U.S. Department of Energy (DOE), DOE Order 458.1 the Total Effective Dose (TED) it is not possible to "measure" the dose during remediation activities (DOE, 2011). While there are plentiful radiation detectors that can measure external dose, there are no detectors available that can measure TEDE or TED. Even if such a detector was somehow magically created, you would need a time machine in order to ensure the TEDE or TED was not exceeded 1000 years post decommissioning in the case of 10 CFR 20 Subpart E.

Therefore, there is a disconnect between the regulatory requirement, which is generally given in terms of TEDE or TED, and the quantity of the contaminant in the environment, which for radionuclides is given in terms of activity or activity per unit mass of the medium that the radionuclide is in.

Converting dose to concentration

Environmental pathways and scenario development

To alleviate this disconnect, it is necessary to convert these dose-based decommissioning criteria to an activity-based criteria. These activity-based criteria are typically measured as a concentration in terms of activity and the mass of the media of interest. For example in soil, the concentration in SI units would be Bq/kg or pCi/g in conventional units.

To perform this conversion it is necessary to estimate the intake of the radionuclide by an individual from inhalation, ingestion as well as estimating the external dose a person would receive. While the external and inhalation pathways are somewhat straightforward, the ingestion pathway can get complicated. Typically the ingestion pathways consider:

- ingestion of plant foods grown on site,
- ingestion meat and poultry products,
- ingestion of milk or other dairy products,
- ingestion water from a nearby well or surface water body,
- ingestion of fish and other aquatic organisms from a surface water body,
- Ingestion of soil.

These additional sub-pathways can get even more complicated? What if the water was used to irrigate the plants, or feed the cattle? These pathways can be represented graphically as those shown in Fig. 1.

In each of these sub-pathways it is necessary to estimate the concentration of the radionuclide in each media. These estimates require the use of mathematical models described by many different variables or input parameters. For example, to estimate the amount of radionuclides taken up by the plant through the roots, one can use a simple plant to soil transfer coefficient although more complex models that take into account the metabolic processes by the plant could be developed. However, to model the amount of radionuclides in the water, more complex models are typically required. Some of these models take into consideration

Fig. 1 Graphical representation of the ingestion pathway and a few of its sub-pathways. Yu C., Zielen AJ, Cheng J-J et al. (2001). *Users Manual for RESRASD Version 6*, ANL/EAD-4, Argonne, IL: Environmental Assessment Division, Argonne National Laboratory.

the chemical form of the radionuclide, the distance from the contaminated site to the well, the depth of the well, the total pore space of the soil, the distance to the aquifer, as well as other factors.

In addition to modeling the migration of the radionuclides through the environment, the dose to the individual is ultimately based on the behavior of the person that may be exposed to the contaminated site. It should be obvious that an individual who may live permanently at the site, grows and raises all of their food on the site, obtains their drinking and irrigation water on the site, would receive a larger dose than a person who may only visit the site one or two times a month for recreational activities (hiking, playing sports etc.). The person living on the contaminated area would spend more time on the area compared to a visitor, ingest a greater fraction of their drinking water while living on the site and perhaps consume a greater fraction of their fruits, vegetables, meat and milk products compared to someone living elsewhere.

Therefore, estimating the dose to an individual and thereby determining the ultimate residual contamination levels will be based upon the scenario analyzed and the site-specific attributes of the contaminate and surrounding media. In addition both 10 CFR 20 Subpart E and DOE Order 458.1 specify ALARA (NRC, 2018; DOE, 2011). This has typically been interpreted as, when possible one should perform additional remediation activities if those additional remediation activities do not incur substantial competing risks.

Determining the cleanup criteria

Once the scenario(s) have been selected and the data collected, analyzed and turned into input parameters, the mathematical models are then used to estimate the dose. The estimated dose a receptor receives is linearly related to the concentration of the radionuclide in the media of interest. For example if 3700 Bq/kg of ^{123}A in the soil resulted in a dose of 1 mSv at a particular point in time, then the dose associated with 1850 Bq/kg of ^{123}A would be $\frac{1}{2}$, or 0.5 mSv, at the same point in time given the same scenario and parameter inputs.

As a notional example lets say a dose assessment is conducted on a site once again containing our hypotheical radionuclide ^{123}A . Based on the scenario analyzed and the data collected the maximum annual dose to an individual was 0.2 mSv/yr for a unit concentration of 1 Bq/kg. Using a 0.25 mSv/yr dose constrain, the cleanup criteria would be:

$$\text{Cleanup Criteria} = \frac{0.25 \text{ mSv/yr}}{\frac{0.2 \text{ mSv/yr}}{1 \text{ Bq/kg}}} = 1.25 \frac{\text{Bq}}{\text{kg}} \quad (1)$$

Note that the annual dose cancels leaving only concentration, which can be often times easily measured. So to continue our example if a site was determined to have an average concentration of ^{123}A of 2 Bq/kg then remediation is required. However if a site had an average concentration of ^{123}A of 0.75 Bq/kg then remediation activities may not be required. As noted above the actual cleanup criteria will be based on ALARA as well as any presence of localized elevated radionuclide concentrations. The implementation of radionuclide cleanup criteria is beyond the scope of this chapter.

The general form for the cleanup criteria each radionuclide can be written as:

$$\text{Cleanup Criteria} = \frac{\text{Dose limit}}{\frac{\text{Maximum Dose}}{\text{Initial Concentration}}} \quad (2)$$

As described in the example the maximum dose is often used in the development of cleanup criteria. As noted in 10 CFR 20 Subpart E (NRC, 2018):

When calculating TEDE to the average member of the critical group the licensee shall determine the peak annual TEDE dose expected within the first 1000 years after decommissioning.

While perhaps non-intuitive, the maximum dose may not necessarily occur early on but may occur one hundred years or more into the future. These phenomena may result due to the time required for the radionuclides to transport to the groundwater. For

Fig. 2 Notional example of the dose associated with two radionuclides and the total dose over time.

radionuclides with short half-lives, the maximum dose typically occurs early on, however for longer-lived radionuclides the maximum dose may occur later in time.

Consider the notional example where a site is contaminated with our hypothetical radionuclides ^{123}A and ^{456}Bx . As shown in **Fig. 2** ^{123}A reaches its maximum dose at $T = 0$ years while ^{456}Bx has its maximum dose at $T = 1000$ years. In this case the cleanup criteria for ^{123}A would be based on its dose at 0 years while ^{456}Bx would be based on its dose at $T = 1000$ years. Note that in this case the total dose only reaches its maximum at the two extreme timeframes. If a site has many radionuclides present, the time for each radionuclide to reach its maximum dose may differ from each other. The implementation of cleanup criteria based on this situation where the time to the maximum dose is different for different radionuclides can become quite complex.

Assessment tools

Most radiological assessment models contain dozens if not hundreds of input parameters used to describe the transport of the radionuclides through the environment, the scenario used to describe human activities at the site post remediation such as a resident farmer or recreational use scenario, and parameters describing how the radionuclides are brought into and metabolized in the human body. While desirable it is not often possible to have site specific or even scenario specific information available for each input parameter. For input parameters where site-specific information is not readily available most dose assessment professionals will use “conservative” values so that any assessed radiological doses would not be underestimated. However, being too conservative or not collecting site specific data could lead to clean up criteria that is either unattainable or may result in competing risks where the actions of cleaning up a site to extremely low levels may result in greater risks from transportation-related activities.

Fortunately tools have been developed to assist in data collection activities and to determine the importance of the various input parameters. There are two classes of tools

1. deterministic analysis and
2. probabilistic analysis.

Deterministic sensitivity analysis is the simplistic of the two classes. In deterministic sensitivity analysis a parameter or several parameters are increased by a specific value compared to its input value. The same set of parameters are then decreased usually by the same factor and the model is run again. This method of sensitivity analysis is called the direct perturbation method. The dose associated with the upper, base, lower parameter values are compared. If the dose does not change significantly or the time of the peak dose does not change significantly the parameter is not considered sensitive and resources do not have to be spent collecting information on this parameter. However if there are significant changes in the dose then that parameter is considered sensitive and resources should be directed at collecting data on that parameter or perhaps that parameter should be set to a more “conservative” value. Note that this chapter does delve into what is considered “significant.” An example of deterministic sensitivity analysis using the direct perturbation method is shown in **Fig. 3**. Note that the dose changes by a factor of approximately two when the thickness of the contamination is changed by a factor of two.

A drawback of deterministic sensitivity analysis is that it is not possible to investigate the interrelationships among parameters. Some parameters are inherently coupled such as the total porosity of the soil and the soil density. As the total pore space of the

Fig. 3 RESRAD implementation of deterministic sensitivity analysis via the direct perturbation method. Yu C., Zielen AJ, Cheng J-J et al. (2001). *Users Manual for RESRAD Version 6*, ANL/EAD-4, Argonne, IL: Environmental Assessment Division, Argonne National Laboratory.

soil increases, the density of the soil would decrease. While one can perform direct perturbation on both of these parameters it is not possible to see the impact of increasing the total porosity while simultaneously decreasing the soil density. Probabilistic analysis is required to effectively investigate the sensitivity of parameters that are related to other parameters. However, interpreting the results of a probabilistic analysis can be challenging even for the most experienced dose assessment professionals.

In probabilistic analysis each parameter that undergoes analysis is assigned a probability distribution. Furthermore, relationships between the various parameters must be specified. In the total porosity vs density example a negative correlation would be provided, so that as the total porosity increases the density would decrease. The strength of the correlation is provided through the correlation coefficient. A positive correlation coefficient will pair parameter values such that as one parameter increases the other parameter will increase. A negative correlation coefficient will pair low parameter values of one parameter with high parameter values of another. A zero correlation means that the parameters are not correlated whatsoever.

One of the challenges is determining the statistical distribution used to characterize the parameters. While there are documents available that have data specific to certain computer codes, these may not represent the site you are modeling or the computer code you may be using. In addition, these statistical distributions must be numerically approximated so they can be used in mathematical models. The method used to approximate these distributions can result in the generation of hundreds of values thereby requiring hundreds of simulations. Therefore, depending on the complexity of the model and whether the model has been optimized for modern computers, the runtime for a complex probabilistic problem with hundreds of approximations for each input parameter can be excessive.

Another challenge is interpreting the output, of the computer generated of simulations when there are hundreds of results to review and analyze. While there are some statistical tools available, some of these advanced tools may not be intuitive to the casual user. Furthermore these statistical tools have difficulty in analyzing non-linear behaviors which can often occur when the dose is very sensitive to small changes in the parameter value in a small subset of its possible values.

Available computer codes

Computer programs are commercially available to assist in converting dose-limits to activity-based concentrations. The remainder of this chapter will discuss the more common computer programs available to users. The computer programs are used to develop site-specific activity concentrations based on site-specific data. Data collection and analysis is imperative to generate site-specific

cleanup criteria. For example using the wrong data for radionuclide solubility could lead to an over or underestimation of dose especially if the use of on-site water is considered in the scenario. It is up to the user to check the validity of the scenario and the data input into the program.

RESRAD family of computer codes

The RESRAD family of computer codes is developed by Argonne National Laboratory to analyze potential dose to humans and biota from residual radioactivity in the environment. (RESRAD, 2019) The computer codes use a pathways analysis methodology to estimate radiological dose and risk over three major exposure pathways: external pathway, inhalation pathway and the ingestion pathway. The estimated dose when compared to regulatory limits or guidelines can then be used to estimate cleanup criteria for the radionuclides that were analyzed. The RESRAD-ONSITE code was the first member of the RESRAD Family, and was simply known as RESRAD (RESidual RADioactivity) (RESRAD, 2019).

Since the development of the initial RESRAD computer codes, Argonne has developed and maintained RESRAD-OFFSITE, RESRAD-BUILD, RESRAD-RDD and RESRAD-BIOTA (Fig. 4). There are other RESRAD codes that have been developed but are not currently maintained, these include RESRAD-RECYCLE, RESRAD-BASELINE, RESRAD-CHEM and RESRAD-ECORISK.

RESRAD-ONSITE

As stated above, RESRAD-ONSITE or simply RESRAD was the initial member of the RESRAD Family of Computer codes (Yu et al., 2001). The code was initially developed in the late 1980's and has been widely used both in the United States as well as internationally. The code is the only code specifically mentioned in DOE ORDER 458.1 regarding the development of authorized limits (i.e. cleanup criteria) (DOE, 2011). The code, is a scenario driven, pathways analysis program that looks at nine exposure pathways (Fig. 5) that include

Fig. 4 Current members of the RESRAD Family of Computer Codes. RESRAD (2019) *RESRAD Family of Computer Codes*, <http://resrad.eva.anl.gov>.

Fig. 5 Graphical Representation of the exposure pathways in RESRAD Yu C., Zielen AJ, Cheng J-J et al. (2001). *Users Manual for RESRAD Version 6*, ANL/EAD-4, Argonne, IL: Environmental Assessment Division, Argonne National Laboratory.

1. direct external radiation,
2. inhalation from airborne radionuclides,
3. incidental soil ingestion,
4. ingestion of plant foods grown in contaminated soil, and irrigated with contaminated water,
5. ingestion of meat produced by livestock fed with contaminated fodder and water,
6. ingestion of milk produced by livestock fed with contaminated fodder and water,
7. ingestion of drinking water from a well or pond adjacent to the contaminated area,
8. ingestion of aquatic foods from the pond, and
9. inhalation of radon emitted from contaminated soil.

The RESRAD code contains features that aid users in developing data sets including sensitivity analysis using the direct perturbation method and uncertainty analysis using standard “Monte Carlo” or Latin Hypercube sampling. The results of the RESRAD simulations are provided in both graphical and standard text outputs. As part of the textual output RESRAD will calculate the individual radionuclide cleanup criteria (soil guideline in the RESRAD summary report) based on a user-defined dose-constraint.

A major benefit of RESRAD is the imbedded features that allow users to perform sensitivity analysis and probabilistic analysis on the input parameters. While it is desirable to have site or scenario specific data associated with each parameter often this is not practiced. Therefore, as mentioned previously, sensitivity and probabilistic analysis is often used to prioritize data collection activities so that adequate resources can be provided on the most important parameters. Data analysis tools exist for both determinist sensitivity analysis and probabilistic analysis.

To help guide the user in developing site-specific parameter values, or to use as a starting point in their analysis, Argonne has an extensive library of supporting documents specific to RESRAD-ONSITE, such as the “Data Collection Handbook, “Development of the Probabilistic RESRAD 6.0 and RESRAD-BUILD 3.0 Computer Codes (NUREG/CR-6697)” as well as a host of other documents.

RESRAD-OFFSITE

RESRAD-OFFSITE extends the capabilities of the RESRAD-ONSITE computer code (Yu et al., 2007). With RESRAD-OFFSITE the receptors no longer has to be co-located with the contaminated site. This expands radiological assessment capabilities such that the well or off-site water body is no longer directly adjacent to the contamination and could be several hundred meters to several kilometers away. Similarly, the areas where crops and livestock reside may be away from the contaminated area or be partially on the contaminated area (Fig. 6). A Gaussian plume model was incorporated into RESRAD-OFFSITE to calculate air concentrations for an off-site receptor and an accumulation model was developed to account for the buildup of radionuclides associated with off-site deposition, while irrigating with contaminated water.

Additional models above and beyond those implemented in RESRAD were developed for RESRAD-OFFSITE specifically those models that consider the accumulation of radionuclides in uncontaminated areas (Yu et al., 2007). However the situation is more complicated in that in addition to accumulating radionuclides in off-site areas, RESRAD-OFFSITE will also model the release those radionuclides based on the chemical properties of the radionuclides and soil type. For example, RESRAD-OFFSITE will model the accumulation of radionuclides to off-site growing areas through irrigation. Simultaneously, as those radionuclides are accumulating they are also being leached out of the surface soil using similar models as those found for the release of radionuclides in RESRAD (Fig. 7).

Similar to RESRAD-ONSITE the results of the RESRAD-OFFSITE simulations are in the form of both text and graphics display. However unlike RESRAD-ONSITE, the radionuclide cleanup criteria must be calculated outside of RESRAD-OFFSITE using Eq. (2). RESRAD-OFFSITE has the same capabilities for deterministic sensitivity analysis and enhanced probabilistic sensitivity analysis.

RESRAD-BUILD

RESRAD-BUILD is a computer code designed to estimate the dose to persons occupying buildings (Yu et al., 2003). Unlike standard pathway analysis tools that model the environmental transport of radionuclides from the soil to the food products, RESRAD-BUILD models the interior movement of radionuclides from room to room by a series of compartment models. The external dose is modeled based on the location of the individual relative to the radiological sources. Unlike RESRAD-ONSITE or RESRAD-OFFSITE there where only one source is modeled at a time, up to 10 sources and 10 receptors can be modeled in a single simulation. The sources include, point, area and volumetric sources. Sources can be co-located such that a point source can be collocated on top of an area source to model “hot spots” or an area source can be modeled on top of a volume source to represent surface contamination on top of volumetric contamination. Since the user can specify up to 10 receptors, the program is flexible such that the receptors can be a single individual located at various spots within a building to estimate an annual individual dose, or several receptors inside a building to estimate a collective dose.

The user must specify air exchange rates between the rooms and with the outside. The underlying assumption is that the outside air is not contaminated. RESRAD-BUILD calculates airflow based on the room height, room area and airflow between rooms. For example a two story house with a basement could be modeled by setting the airflow with the basement to the outside as $0 \text{ m}^3/\text{h}$ (Fig. 8).

The total dose to the receptor(s) is a linear combination of the radiation dose associated with each source. Since the dose to the receptor is based on the total amount of time present at that location, the units for dose are in mSv as opposed to mSv/yr. However if the user is modeling a situation where the receptor is to represent a person exposed for a year, the dose can be interpreted as mSv/yr.

Fig. 6 Map interface for RESRAD-OFFSITE. The size of the icons scale with area, in this case the pond is further from the contamination area. All residential and growing areas are away from the contaminated zone and would rely on the accumulation models built into the program to calculate concentration and therefore dose. Yu C, Gnanapragasam E, Biwer BM, Kamboj S, et al. (2007) *User's Manual for RESRAD-OFFSITE Version 2*, ANL/EVS/TM/07-1, DOE/HS-0005, NUREG/CR-6937, Argonne, IL: Environmental Science Division, Argonne National Laboratory.

Fig. 7 Radionuclide concentration versus time for an off-site pasture due to irrigation. At time $T = 0$ to approximately $T = 300$ years there is no contamination present. After $T = 300$ years (the amount of time required for the radionuclides to reach the well in this instance) radionuclide concentration steadily increases. Yu C, Gnanapragasam E, Biwer BM, Kamboj S, et al. (2007) *User's Manual for RESRAD-OFFSITE Version 2*, ANL/EVS/TM/07-1, DOE/HS-0005, NUREG/CR-6937, Argonne, IL: Environmental Science Division, Argonne National Laboratory.

Since RESRAD-BUILD is flexible in its capability to model either individual or collective doses for multiple sources, the program does not calculate cleanup criteria like the RESRAD computer code. Therefore, cleanup criteria must be developed for each source/receptor combination using a Eq. (2). The units associated with the cleanup criteria are dependent on the type of source (Bq for a point source, Bq/m² for an area source and Bq/kg for a volume source).

DandD computer program

The DandD computer code is an environmental pathways analysis program developed by Sandia National Laboratories to implement the methodology found in NUREG/CR-5512 Volume 1 Residual Radioactive Contamination From Decommissioning, Technical Basis for Translating Contamination Level to Annual Total Effective Dose Equivalent (Kennedy and Strenge, 1992; McFadden et al., 2001). Specifically the methodology was developed for U.S. NRC licensees who needed to decontaminate lands and structures to acquire unrestricted use of their properties based on a 0.25 mSv/yr public dose limit. The program has two built in scenarios, the "Residential" and "Building Occupancy." "DandD Version 2.1 incorporates probabilistic analysis into the two scenarios (McFadden et al., 2001).

The "Residential" scenario models the a site with surface soil contaminated soil and considers the following pathways:

1. direct external radiation,
2. inhalation from airborne radionuclides,
3. incidental soil ingestion,
4. ingestion of plant foods grown in contaminated soil, and irrigated with contaminated water from a well,
5. ingestion of beef produced by livestock fed with contaminated forage, stored grain, stored hay and water from a well,
6. ingestion of milk produced by livestock fed with contaminated forage, stored grain, stored hay and water from a well,
7. ingestion of poultry fed with contaminated forage, stored grain, and water from a well,
8. ingestion of eggs where the poultry is fed with contaminated forage, stored grain, and water from a well, and
9. ingestion of drinking water from an on-site well.

The "Building Occupancy Scenario" models surface contamination within a building. The exposure pathways include

1. direct external radiation
2. inhalation from resuspended surface contamination
3. inadvertent ingestion of surface contamination
4. external exposure from submersion of dust particles
5. internal contamination from puncture wounds
6. dermal absorption and
7. inhalation of radon.

While DandD is a pathways analysis model, and are conceptually appear the same as those in RESRAD and RESRAD-OFFSITE, the models in the DandD computer program are less complex than those in RESRAD-OFFSITE, RESRAD and RESRAD-BUILD. These simplifications may lead to an overall larger dose to a receptor for similar exposure conditions. For example RESRAD and RESRAD-OFFSITE allow up to five distinct unsaturated layers below the contaminated zone whereas the DandD code only allows for a single unsaturated layer. In addition the user may specify that the contamination layer is buried below clean cover in RESRAD and RESRAD-OFFSITE whereas the DandD program only calculates surface soil contamination for the "Residential" scenario.

Regardless of the computer codes used for radiological assessments, it is important that users understand the limitations of the program and the inherent assumptions built into the models. For example while it would appear that RESRAD could be used to

directly model an engineered landfill, this is not the case due to the complexities involved in the various engineered barriers encounter in a disposal facility. In this instance RESRAD-OFFSITE may be more applicable due to the availability of multiple types of leaching models built into the program.

Other computer programs

The computer programs discussed previously assumed that soil was initially contaminated by some means. The manner by which the soil was contaminated is beyond the scope of the computer models. However, it may be necessary to perform radiological assessments for working facilities or to perform a dose reconstruction after an event such as an unexpected airborne release. We will discuss two programs CAP-88 PC and GENII, keep in mind that other site-specific models may be developed for large or high-profile public releases of radioactive material.

CAP-88 PC

The CAP-88 (Clean Air Act Assessment Package - 1988) computer model is a set of computer programs, databases and associated utility programs for estimating dose and risk. (EPA, 2019) CAP-88 is a regulatory compliance tool under the National Emissions Standard for Hazardous Air Pollutants (NESHAP). Dose and risk estimates from CAP-88 PC are applicable only to low-level chronic exposures, since the health effects and dosimetric data are based on low-level chronic intakes. CAP-88 PC cannot be used for either short-term or high-level radionuclide intakes.

CAP-88 uses a modified Gaussian plume model to estimate dispersion and ultimately air and ground concentrations from six sources (EPA, 2019). The sources can be modeled as elevated releases (stacks) or ground level releases such as piles of contaminated soil. Radiological risk assessments are performed for a circular grid of 16 sectors by setting distance and direction within a radius of 80 km (50 miles) around the facility. The pathways considered in CAP-88 include:

1. inhalation of airborne radionuclides,
2. inhalation from radionuclides attached to resuspended dust,
3. ingestion of leafy vegetables,
4. ingestion of milk,
5. ingestion of meat products,
6. external dose due to deposition,
7. external dose due to air submersion.

Note that there is no drinking water pathway or water pathways associated with irrigation. The dose and risk estimated using CAP-88 is based on annual radionuclide releases to the air and therefor the doses associated with ground water associated with radionuclide transport through the underlying soil would be considered a minor component when compared to the primary airborne release from a facility.

GENII

The GENII computer program is a suite of computer models integrated through the FRAMES software package (Napier et al., 2012). There are separate models for airborne and waterborne releases. The airborne release is similar to that of CAP88 however in addition to estimating doses and risks from routine normal operations, the GENII atmospheric transport model can estimate radiological dose and risk from acute releases from accidents. For the atmospheric transport model, GENII uses both a Gaussian plum and Lagrangian puff model depending if the release is either a chronic or an acute release.

The surface water module is included to represent transport through surface waters to the terrestrial environment. (Napier et al., 2012) The models include acute and chronic releases to non-tidal rivers and chronic releases to near shore lake environments. The mechanism of how the radionuclides are released to these media is beyond the scope of GENII. The user must specify release rates of the radionuclides to the air and water modules.

The atmospheric module and surface water modules are then coupled to the receptor intake module and health impact module to estimate dose and risk. Therefore depending on the problem set analyzed (airborne release, water release, or both) the pathways analyzed include (Napier et al., 2012):

1. External exposure
 - a. due to plume immersion
 - b. ground deposition
 - c. while swimming
 - d. exposure while boating
 - e. exposure at the shoreline
2. Inhalation
 - a. Contaminated air
 - b. Resuspended radionuclides on dust
 - c. Indoor air

3. Ingestion
 - a. Terrestrial farm product
 - b. Aquatic food
 - c. Drinking water
 - d. Inadvertent soil ingestion
 - e. Inadvertent water ingestion while swimming
 - f. Inadvertent ingestion while showering

Conclusion

Computer models are required to demonstrate compliance with applicable regulatory requirements for the exposure to members of the public from contaminated sites. Regulations are typically written in terms of dose or annual dose-rate to a member of the public. Radionuclide concentrations are typically measured prior to and during remediation activities, therefore a relationship between concentration and dose must be established. This is compounded by the fact that many times the regulations specify annual dose limits out into the future such as 1000 years.

There have been several computer programs written to estimate radiation dose to members of the public from contaminated land. The most prevalent is the RESRAD Family of Computer Codes. This suite of computer codes allows users to either estimate dose or clean up criteria associated with radiologically contaminated sites. Depending on the receptor location, whether on-site, off-site or within a building, there are individual computer programs available for each application. However, there are other codes available such as the DandD computer program, which is similar to RESRAD, as well as the CAP-88 and GENII computer programs. Unlike RESRAD and DandD, CAP-88 and GENII are typically used to estimate doses associated with chronic (CAP-88 and GENII) or acute releases (GENII) and are not typically used for environmental remediation activities.

It is up to the user to determine the applicable computer programs. Typically all radiological dose assessment programs estimate radiological dose and/or risk associated the main exposure pathways (external, inhalation and ingestion) however, the manner in which they estimate these doses and the underlying models and assumptions that go into the programs can be quite different.

Introduction

Sites involved in the nuclear fuel cycle and nuclear power generation, legacy sites from atomic weapons development and production, nuclear research in both private sector and national laboratories, specialized industrial products, and others are required to operate in accordance with radiological protection standards, licensing or other regulatory requirements in effect at the times of operation. When the facility concludes its mission, the cessation of activities under typical scenarios result in the facility seeking release from radiological and regulatory control where the desire may be to sell or otherwise transfer the property for future use without radiological restrictions. However, because of the historical radioactive material use, the default assumption is that these materials impacted (contaminated) the facilities themselves—i.e. structures, equipment, systems—as well as the external environment.

Therefore, prior to a site release being authorized, the status and regulatory requirements migrate from operations into decontamination and decommissioning (D&D). The ultimate objective of D&D is to either clean up residual radiological contamination or otherwise confidently prove that any residual contamination is less than the applicable criteria that must be met to release the site without radiological restrictions. When the criteria cannot be met, the site may either have a conditional release that includes some type of institutional controls or restrictions on future use, or will remain under regulatory control.

Prior to the cognizant regulatory authority granting the site release, the site must provide adequate documentation showing that the facility satisfies the release requirements. The release may be authorized in the form of license termination for those facilities licensed by the U.S. Nuclear Regulatory Agency (NRC) or an Agreement State. An Agreement State, per the NRC, is a state that assumes NRC regulatory authority under the Atomic Energy Act of 1954, as amended and provides a statutory basis under which NRC relinquishes to the States portions of its regulatory authority to license and regulate byproduct materials (radioisotopes); source materials (uranium and thorium); and certain quantities of special nuclear materials. In addition to State or Federally licensed private sector sites, U.S. Department of Defense (DOD) facilities in many cases also operated under NRC licensing while U.S. Department of Energy (DOE) sites are regulated within the Department itself. State agency stakeholders, although not the regulator of record, are also generally involved with DOE and DOD sites within their borders that are undergoing decommissioning. Furthermore, if the site is within the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), the U.S. Environmental Protection Agency (EPA) is also involved in oversight.

Historically, the guidelines to demonstrate that a facility could be released to the public or other uses were based on the sensitivity of the instrumentation available at the time to detect and quantify the radiation of concern. The NRC issued a new license termination rule in 1997 that revised their licensee's requirement for license termination from meeting a table of residual contamination values to a dose based limit of 25 millirem per year (0.25 milliSieverts). With this change, the D&D requirements and cleanup guidelines have since become more advanced, most notably in how the cleanup criteria are derived, where they are now derived using either default or site-specific inputs to satisfy the annual dose limits or other decommissioning criteria. The cleanup criteria are referred to as derived concentration guideline limits (DCGLs). The NRC published screening level DCGLs (NRC, 2006) for select radionuclides for allowable residual activity on building surfaces in units of disintegration per minute per 100 square centimeters (dpm/100 cm²) and for soil in picocuries per gram (pCi/g) (Note: SI equivalents can only be provided for a specific DCGL value.) The DCGLs—actually denoted as the DCGL_W—are the allowable average concentration of each contaminant within the survey unit. Because it is an average value, some individual samples may exceed the DCGL_W, which is acceptable in many cases, provided the average including hot spot contributions is less than the DCGL_W. Additional information regarding hot spot requirements are provided later in this chapter.

Agreement State dose limits are at least equivalent to NRC's or more restrictive, with some states essentially requiring no dose in excess of background. The DOE Order 458.1 (DOE, 2011) provides requirements for the development of site-specific authorized limits or application of pre-approved limits also in terms of dpm/100 cm² and pCi/g. The DOE limits differ from those of the NRC's and are based on DOE-specific requirements for radiological protection of the public and environment. The EPA requires their own risk based limits which results in different release criteria from those of the NRC. Because EPA may also have regulatory involvement with some NRC licensee's there can be conflicting requirements the site must meet. To minimize these conflicts, a memorandum of understanding (MOU) was established between the two organizations. Similar guidelines exist for other countries, where many countries have adopted the International Atomic Energy Agency's (IAEA) standards for clearance or exemption of materials (IAEA, 2005).

A major component of the decommissioning is the remediation of radioactive contamination to reduce contamination levels within structures equipment, and impacted environmental media until radiological measurements and samples confidently demonstrate that applicable cleanup criteria have been met. However, prior to commencing remediation, radiological investigations are performed to identify where contamination is present, the levels of contamination, and the media impacted.

The principal steps in the D&D radiological survey and site investigation (RSSI) life cycle of a contaminated site is best described by the Multi-Agency Radiation Survey and Site Investigation Manual (MARSSIM) (NRC, 2001). The investigation steps begin with the historical site assessment (HSA), scoping survey, and characterization survey to identify contaminated areas. Site remediation, when required, follows the characterization survey. The remedial actions will involve processes such as soil excavation, scabbling of concrete surfaces, or other methods. When decontamination is thought to be adequate, a remedial action support survey (RASS) is performed that involves a few qualitative or quantitative measurements. If the RASS investigation indicates successful decontamination, then the final status survey (FSS) is performed and documented. The FSS is formally planned and implemented to satisfy regulatory guidance. The results are documented in a report and serve as the primary evidence submitted to the regulatory authority demonstrating that the decommissioning requirements for license termination or site release have been met. The regulator then determines whether all conditions are satisfied and the site may be released. As part of the release decision, the regulator may elect to perform an independent confirmatory survey to provide additional assurance that results are accurate and reproducible. The RSSI process is illustrated in Table 1.

Further discussion of each investigation is provided below, and includes methods generally included in the design, implementation, and assessment of each.

Historical site assessment (HSA)

A site identified as potentially contaminated begins the RSSI process with an HSA. The HSA is not an actual survey, but rather is thorough records review to gather and review all the information relevant to the site's radiological status. Information reviewed might include the following:

- operational records and data
- interviews with current and previous employees
- aerial photographs
- licensing documents
- facility maintenance or remodeling records
- waste disposal records and material handling routes
- records of spills or effluent releases
- routine survey/environmental monitoring data

Table 1 Principal steps in the D&D RSSI lifecycle.

RSSI Phase	Description
Historical Site Assessment ↓	Document available information to determine if the site is impacted
Scoping Survey ↓	Describe limited confirmation on presence, magnitude, and location of contamination
Characterization Survey ↓	Define the nature and extent of contamination and support remediation planning
Remedial Action Support Survey ↓	Determine if the site is ready for final status surveys; provide inputs for final status planning
Final Status Survey ↓	Demonstrates compliance with the remedial action objectives
Confirmatory Survey	Quality assurance investigation performed by or on the behalf of the regulatory agency

The HSA goal is to paint a complete picture as possible in the form of a conceptual site model (CSM), identifying the different portions of the site that could be impacted by radioactive material from historical site operations and waste disposal practices. If possible at this early stage, the CSM includes preliminary contamination potential classifications for impacted areas. The definitions from greatest to least contamination potential are:

Class 1: potential to contain or at one time contained contamination in excess of the DCGL_W;

Class 2: potential to contain contamination but at concentrations less than the DCGL_W.

Class 3: potential to contain contamination, but at a small fraction of the DCGL_W.

Fig. 1 shows an aerial photograph of a site that was involved in storing radioactive material in warehouses. The second image is a graphic of the site plot plan showing how the land areas and structures were preliminarily classified following the HSA.

A primary reason for classification is to provide a mechanism for determining where future resources would be expended. Areas with the greatest contamination potential will receive the greatest effort. If there is insufficient information, all areas may have to be designated as Class 1 until adequate data are obtained. Other HSA objectives are to:

- major contaminants and relative ratios among multiple contaminants (for DCGL_{Ws})
- contaminants chemical/physical form (for DCGL_{Ws})
- time since operations and material use (short-lived radioactive material decayed and is no longer a potential contaminant or for progeny in-growth for chemically separated radionuclides such as uranium or thorium)
- identify potential contaminated media:
 - Surface soil
 - Subsurface soil
 - Building surfaces
 - Process equipment
 - Support equipment
 - Other media

An alternative to an impacted classification is when an area might be considered non-impacted. Non-impacted areas have no reasonable potential for contamination, and therefore do not require further investigation to support release. In reality, stakeholders are many times hesitant to accept the non-impacted status without at least some data to support the decision. Therefore, many D&D sites perform a limited scope survey.

It is expected at the completion of the HSA that there will knowledge gaps requiring further investigation. The conclusions reached and identified gaps serve as inputs to planning the next phase, the scoping survey.

Scoping survey

The scoping survey objectives are to validate, refine, or refute the preliminary site status from the HSA. Where the HSA was a paper-work exercise, the scoping survey requires field work across the site. The level of effort or the focus given to each area is based on a graded approach. The graded approach simply means that the most survey and sampling effort is expended toward those areas with the greatest potential for contamination, areas with the most unknowns or data gaps, or a combination thereof.

The scoping survey design consists of cursory radiological surveys, primarily qualitative scan surveys, and the collection of a limited number of judgmental measurements or samples, although under certain circumstances more rigorous, statistically-based scoping surveys may be planned. The data collected serve to confirm the impacted or non-impacted status, and in impacted areas, confirm types, levels, and variability of contaminants present and substantiate area classifications. Other scoping survey objectives might include hazard assessments or identifying background reference areas.

The instrumentation used for the scoping survey are selected based on the radiation emissions of the contaminants. For sites with gamma-emitting radionuclides of concern (ROC), gamma walkover scans of land areas and building surface scans are most commonly performed using sodium iodide (NaI) scintillator detectors. **Fig. 2** shows surveyors performing gamma walkover scans with NaI detectors coupled to global positioning system (GPS) equipment. The surveyor listens via the audio output for elevated radiation count rates. The GPS equipment continuously captures both the count rate and geo-referenced position data for spatial evaluation. The GPS and radiation detector systems mounted are also commonly mounted onto vehicles when surveys of large land areas are required.

Building surfaces are also scanned for alpha and/or beta radiation based upon the suspected ROCs. The main detector types for alpha scanning of surfaces, are gas-flow proportional counters and zinc sulfide (ZnS) scintillators. Gas-flow proportional, pancake Geiger-Mueller (GM), or plastic scintillator detection systems are used for beta scans.

As indicated, the land and building surface scans are intended to identify radiation anomalies. When suspect contamination is identified on a building surface, an alpha/beta surface activity measurement or sample for laboratory analysis is collected. Similarly, a soil sample is collected from land area anomalies. These samples and measurements that are based on scan results are examples of judgmental sampling. That is, based on experience, professional judgment, or preliminary results, the surveyor goes to areas expected to have the highest likelihood of contamination. Some random sampling may also occur during scoping.

How the graded approach is applied to determine scan coverage for land or building surfaces or an appropriate number of judgmental and/or random samples or measurements provides the opportunity to introduce the concept of data quality objectives

Fig. 1 Aerial site view and conceptual site model plot plan showing site classification.

(DQOs). DQOs are a critical component of the MARSSIM guidance for planning final status surveys. The application of DQOs throughout the RSSI process help ensure the right quantity and quality of data are collected for decision making. EPA provides additional information on DQOs in an excellent environmental data collection guidance document (EPA, 2006). The next section further explains DQOs.

Fig. 2 Surveyors performing gamma radiation walkover scans. From: <https://www.ornl.gov/environmental-assessments/index.html>.

This scoping survey discussion concludes by introducing the data quality assessment (DQA) phase. There may be multiple data objectives, dependent upon the DQOs. Again, one of the primary scoping survey objectives is to confirm the HSA's preliminary classification of areas, or otherwise modify/refine the CSM. The absence of contamination in collected data may be evidence that the area is indeed Class 3 or should be reclassified as Class 3. Under certain scenarios, when sufficient information is available for a Class 3, the scoping survey may be designed to also satisfy the FSS. In other words, skip ahead from the HSA directly to the FSS. This is only advisable when confident in the classification and instrumentation and procedures satisfy FSS requirements. Alternatively, contamination is confirmed or otherwise identified and the area is reclassified as Class 1 or 2.

Data quality objectives

The seven-step DQO process helps ensure that the type, quantity, and quality of the survey data used in decision-making are appropriate for its intended use. The DQO steps are:

- Step 1. State the problem.
- Step 2. Identify the decision.
- Step 3. Identify inputs to the decision.
- Step 4. Define the study boundaries.
- Step 5. Develop a decision rule.
- Step 6. Specify limits on decision errors.
- Step 7. Optimize the design for obtaining data.

Table 2 lists each step, what the step involves and provides a simplified approach using a scoping survey scenario for investigating a preliminary classification for a site area as Class 3.

Characterization surveys

Site characterization can be complex and because sites and therefore study objectives are unique, there is no single method upon which to base a default process. Because of this, DQO application is critical. The American National Standards Institute (ANSI) and the Health Physics Society developed an industry standard for DQO application to characterization. According to both MARSSIM and ANSI N13.59, the characterization survey is the most comprehensive of all survey types and generates the most data (ANSI, 2008; NRC, 2001).

The amount of data needed is because characterization survey data serve many uses beyond just defining the nature and extent of contamination. Some primary characterization data needs are shown in **Fig. 3**. In addition to determining location of contamination, total contaminated surface area or waste volumes, the data often are used in pathway analysis inputs and derived concentration guideline level (DCGL_W) development, remedial action planning support, and even determining the site's final status.

A summary-level discussion is provided here for the characterization purposes with the exception of pathway analysis and DCGL_W calculations addressed in other chapters.

Table 2 DQO steps, description, and examples.

<i>DQO step</i>	<i>DQO step description</i>	<i>Specific example</i>
Step 1. State the problem	Resources also are listed (i.e., the budget, schedule, and personnel) and the conceptual site model (CSM) is presented. However, the main objective of Step 1 is to provide a concise description of the problem	One portion of the entire site that was classified as Class 3 following the HSA Problem Statement: A scoping survey is necessary to validate that HSA that the area is Class 3 and contains contamination at no more than a small fraction ($<10\%$) of the $DCGL_W$
Step 2. Identify the decision	The goal of Step 2 is to define the principal study question (PSQ) that the project will attempt to resolve, identify alternative actions (AAs) that may result from answering the PSQ, and combine the PQS and AAs into a decision statement	PSQ: Are contamination levels less than 10% of the $DCGL_W$? AA1: Yes, maintain the Class 3 designation AA2: No, reclassify to Class 2 or Class 1 based on observed levels Decision Statement: The survey will be performed and the data used to determine the area classification
Step 3. Identify inputs to the decision	The purpose of Step 3 is to identify the information that is required to address each decision statement. Sources of information also are identified	Only HSA records, a screening level $DCGL_W$ are available as inputs Radiological measurements and analytical data for samples are to be generated
Step 4. Define the study boundaries	Step 4 presents spatial, temporal, and practical boundaries to the problem set	The spatial boundaries are the current subdivision of the Class 3 area The temporal boundary is the time period over which the survey must be completed and the data assessed
Step 5. Develop a decision rule	Step 5 provides the specific parameters that will be obtained and how those data are used in making the decision	Decision Rule: If all sample radionuclide concentrations are less than 10% of $DCGL_W$ maintain Class 3 designation, if concentrations are $>10\%$ and $<DCGL_W$ reclassify as Class 2, and if $>DCGL_W$ reclassify as Class 1
Step 6. Specify limits on decision errors	Step 6 presents the basis for saying "how good" the decisions need to be by presenting the null hypothesis and tolerable limits on decision errors	This could include a formal hypothesis statement. With hypothesis testing or any decision there is a chance of an incorrect decision. This example's assumed base condition is a Class 3 area, and evidence is required to overturn that condition and decide the area is Class 2 or 1. The Type I error, or false positive represents the decision confidence. 95% confidence means that there is a 5% chance probability of incorrectly concluding the example area is Class 2 or 1 when it should have remained a Class 3. The Type II error, or false negative, represents the probability of failing to conclude the area is Class 2 or 1 when it should be
Step 7. Optimize the design for obtaining data	Step 7 is used to evaluate Steps 1 through 6 and consider ways to optimize the project design. This step typically specifies the number, location, and type of information required for decisions	Decide investigation coverage, determine sample locations, specify instrumentation, procedures, laboratory analyses and other applicable methods

Define the nature and extent of contamination

The characterization survey fills HSA and scoping survey data gaps to describe the primary contamination. Without this knowledge, remediation planning may be inaccurate, leading to poor decisions, schedule delays, and rework. A proper characterization effort will:

- Identify all radiological contaminants, including any hard-to-detect (HTD) radionuclides mentioned (or not) in the HSA/scoping survey
- Estimate the statistical characteristics (range, average, etc.) of contaminants
- Establish relationships, if any, between contaminant concentrations
- Describe the physical form and distribution of the contamination, such as removable or fixed contamination on structural surfaces, distributed or small areas of elevated contamination in soil, etc. and locations
- Determine whether remediated material will meet the waste acceptance criteria of the selected disposal facility and also transportation requirements for the waste to meet Department of Transportation (DOT) requirements. The IAEA has adopted international regulations for the safe transportation of radioactive material. As a member state, the United States, through DOT

Fig. 3 Characterization objectives.

and NRC, has amended its domestic regulations to make them compatible with the IAEA standards.” Applicable Code of Federal Regulations are [10 CFR Part 71.5](#) Transportation of Licensed Material, (NRC citation of DOT regulations) and DOT requirements are specified in 49 CFR Parts 72 and 73.

From the above list of goals, the following are possible PSQs asked during Step 2 of the DQOs and should emphasize why the characterization plans significantly benefit by applying the DQOs:

- What is the physical form of contamination?
- What are the specific contaminants?
- What is the magnitude of contamination?
- What are the contaminant variabilities, averages, and ranges?
- Are contaminants mixed or isolated?
- What are the contaminated media?
- Are contaminants present in a mobile form?
- Is groundwater contaminated?
- Could groundwater be contaminated in the near future?
- Is contamination surficial or volumetric within structural surfaces?
- Is contamination limited to surface soil or has subsurface soil been impacted? What is the depth of the contaminated layer?
- Are there site-specific conditions—e.g. soil type/porosity, depth to groundwater, etc.—that may impact DCGL_W modeling?
- Are areas candidates for FSS without remediation?

Plan for remedial actions

Characterization results also support remedial action planning to:

- Assess the scope of proposed decommissioning actions
- Support evaluation of alternative decommissioning actions
- Ensure decommissioning worker and public safety
- Evaluate potential environmental releases during decommissioning and determine methods to minimize the occurrence and impact
- Determine the suitability of various survey instruments and analytical procedure and methods
- Estimate post-remedial action (residual) contaminant concentrations
- Determine the type, concentration, and extent of non-radiological contamination
 - Because remediation can remove both radiological and non-radiological contamination, it might not be necessary to assess both in a given area
 - Evaluate the potential for encountering mixed waste or accidentally generating mixed waste—mixed waste can be extremely expensive to disposition

Characterization plan preparation

The DQOs are incorporated into the characterization plan itself. There are a myriad of sampling design choices available when planning an environmental investigation. In principal, the choices expand out from two basic sampling tenets: non-probabilistic and probabilistic.

Non-probabilistic uses non-random techniques to select a sample or its location and includes judgmental (biased/targeted) sampling and convenience sampling.

- As discussed for scoping surveys, judgmental sampling techniques are based on some subjective condition using professional knowledge or experience.
- Convenience sampling—also referred to as opportunistic, haphazard, grab, or accidental sampling—is exactly as the name implies: a location is sampled because it is close by, easy to obtain, or is happened upon while performing other site investigation activities. These are not random samples.

Probabilistic sampling uses random techniques such that every possible subset (sample) has an equal selection probability to represent the population of interest. The sampling plans also account for the expected type of population distribution, normal (parametric) or skewed (non-parametric). Sample placement is either in an ordinary random, systematic, or stratified manner. The plans may also incorporate other techniques that include composite sampling where multiple increments are combined to form one sample for analysis, thereby saving analytical costs, or processes where an inexpensive field screening tool may be used to select samples for more rigorous analysis. All of the common methods are described in another EPA document titled *Guidance on Choosing a Sampling Design for Environmental Data Collection* (EPA, 2002). This guidance has been incorporated into the computer-based sample planning program, Visual Sample Plan (VSP), which is maintained by the DOE's Pacific Northwest National Laboratory (PNNL). The VSP software may be downloaded at no cost from the PNNL-VSP website (<https://vsp.pnnl.gov/>).

Several factors are considered in the judgmental [non-probabilistic] or random [probabilistic] sample planning decision, including level of effort to implement the sample plan, costs, and foremost, the data end-use. Random samples are necessary to optimize the precision, accuracy, and control bias and uncertainty of the measurements used for statistical decision-making and other data evaluations or study result validations. Judgmental samples remain valuable. Judgmental sample results are typically evaluated independently—for example, comparing soil concentrations at a hot spot to action levels or outlier tests—and are not pooled with random sample results for statistical calculations. They may also be useful for specific parameters such as establishing the ratios of radiological contaminants to one another, samples should be collected from locations that have elevated activity rather than from a group of random samples that may only represent background.

Table 3 provides some advantages and disadvantages of the two methods.

Ultimately, one or both of these sample types are collected during the site investigation process. The important thing is to know the data end use and to recognize the differences between a judgmental and random location. The caution is that some plans may not be appropriate for specific problems. In other words, a plan designed to assess the average concentration against an action threshold will not be appropriate for identifying small areas of unacceptable concentrations, also known as not-to-exceed thresholds. As such, the decision that will be made with the data during the DQA is a key factor in selecting the appropriate plan and again spotlights why the DQOs are important.

The type of plan will also determine the number of samples that are required to make a decision and control the decision errors. There are several factors that impact the required number of samples. The most significant sample size input is how close the estimate of the assumed base condition is to the decision action level. In statistical terms, the difference between the assumed base condition and decision threshold is referred to as the gray area. In those instances where the parameter clearly exceeds or is clearly less than the threshold, statistical tests are not necessary. However, when the parameter is within the gray area, things are too close to call. A narrow gray area coupled with a lot of variability in the parameter, i.e. a lot of uncertainty, then a large number of samples is required. Using the example average radionuclide concentration and DCGL_W action level scenario, the closer the average concentration is to the DCGL_W, and the less certainty there is the average estimate, the greater the number of samples required to make a good decision. **Fig. 4** illustrates this idea, as the mean approaches the decision change threshold, the increased uncertainty illustrated with the two curves shows how the uncertainty in the mean estimate extends well past the action level.

Table 3 Comparison of random versus judgmental sample plans.

<i>Random</i>	<i>Judgmental</i>
Advantages	
• Uncertainty calculations • Statistical analysis/inference • Decision error control	• Less expensive to plan and implement • Efficient when site is well known • Provides important information for specific data needs, such as contaminant ratios and maximums
Disadvantages	
• Random locations may be difficult to locate in large survey units • Requires more planning to optimize design	• Requires expert knowledge to acquire targeted information • Not reliable for estimating uncertainties • Depends on subjectivity to interpret study objectives

Fig. 4 Illustration of parameter population distribution: mean, variability, and action level.

Fig. 5 Posting plot (created using Visual Sample Plan, PNNL, 2019).

In addition to characterization sampling to determine remediation requirements, oftentimes there are large portions of the site that will not require remediation. For these areas the characterization plan may be intended to evaluate spatial variability over Class 2 or 3 areas. Information on spatial variability may be extremely beneficial for demonstrating that ROC levels are less than $DCGL_W$ s and optimizing survey unit boundaries. A posting plot is one of the best methods to visualize spatial relationships in the concentrations. Fig. 5 shows an example plot. The values shown are the radionuclide concentrations in the samples collected. The red outline highlights the area with highest concentrations and that may require remediation if greater than the $DCGL_W$, or segregated as a separate FSS survey unit.

Other plans may be designed to estimate the average concentration of an area requiring remediation to ensure waste acceptance criteria (WAC) requirements are met and also identify areas via a systematic sampling method that may require special handling. Fig. 6 is an example VSP plan with sample locations shown. The example plan is a unique method known as ranked set sampling (RSS). It combines random sampling with professional judgment. The goal of this method is to reduce the number of samples required to obtain a as good an estimate of the mean obtained with simple random samples. Note that random sampling would require 27 samples while RSS requires 15 for the same confidence in the mean estimate. EPA (2002) provides more information on RSS.

There are other sample plans that may be developed with and without formal hypothesis tests or thresholds as part of the data assessment. These plans include the following:

- Tests of proportions
- Establish a baseline for trend analyses, a control chart is one example
- Estimate the mean and CI of the mean
- Identify unacceptable areas (e.g., identify presence/absence of hot spots of area $\geq X$ with $Y\%$ confidence)

The plan that is selected for characterization studies varies considerably for each unique site. In most all cases, multiple types of plan are implemented for different site areas, dependent upon the decisions that will be made.

Procedures

The characterization survey procedures depend upon the type of data required as determined during DQO development. Land areas are almost always gamma scanned to identify soil contamination, provided that there are gamma-emitting ROCs. Locations where radiological anomalies are identified or other suspect locations are sampled and the samples submitted to the laboratory for analysis by gamma spectroscopy or various radiochemistry methods. If subsurface contamination is suspected, borehole sampling is performed via various mechanical (drill rigs or direct push sampling) or manual methods using hand augers. The combination of scanning and sampling are used to bound the contamination extents. Fig. 7A–C shows gamma radiation scan data for a contaminated land area, the sample locations collected from the area, and the area after the soil was excavated for disposal. The sampling data were used to determine the excavation boundaries, calculate the total volume of soil requiring remediation, the concentrations needed for comparison to the WAC, and for generating shipping papers.

Fig. 7 (A–C) Gamma radiation scan results, soil sample locations and remediation of a land area.

Buildings undergo a similar process for determining the location and magnitude of contamination. Surfaces are scanned for alpha, beta, and/or gamma radiation followed by direct measurements of the total surface activity levels for comparison with the $DCGL_W$. These measurements are supplemented as determined during DQO development with samples. Samples may include smears or large-area wipe samples to assess the fraction of the total contamination that is removable (loose) and may be easily remediated versus the amount that is fixed to the surface and must be decontaminated via aggressive techniques. Physical samples are also necessary to assess the specific ROC mixture when more than one contaminant is present, or to determine if the contamination rather than being only surficial, has penetrated into the volume of the material. Volumetric contamination also occurs when materials of construction are radiologically activated due to exposure to a neutron field, common with nuclear reactor or accelerator facilities. Fig. 8A and B are images of a floor undergoing investigation. The first image is where a top layer of asphalt that covered the original, contaminated concrete floor, has been marked where elevated gamma radiation was measured, indicating contamination beneath the asphalt. The second image shows floor removal to sample the subfloor surface that became contaminated from liquid migrating through an expansion joint. The third and fourth images are a plot plan showing measurement and sampling locations—color-coded to indicate contaminated area and locations that were less than the $DCGL_W$ —and the same area after remediation.

Remedial action support survey (RASS)

Once the site has been characterized, the focus shifts to completing remediation and the next RSSI phase begins; the remedial action support survey (RASS). The RASS is not necessarily one discrete survey—it may be a combination of several data collection efforts to determine remediation effectiveness in real-time, and verifying characterization phase assumptions (e.g. depth of contamination). An example is performing surface contamination measurements immediately following concrete scabbling to verify that the thickness removed was adequate or in the case of soil, when excavation activities have reached a sufficient depth for contaminated soil removal. The RASS data are used to determine when an area is ready for the FSS. Consider that with remediation, the population distribution, median or mean, and skewness of contamination drastically changes. The average contaminant concentration in a remediated area should certainly go down below the levels seen during characterization. The variability in contaminant

Fig. 8 (A) Areas of elevated direct gamma radiation detected while scanning. (B) Exposed contaminated sub-floor strata, sample collected for laboratory analysis. (C) Characterization results map. (D) Floor slab removed, exposed contaminated sub-floor strata.

concentrations would also be expected to be reduced, i.e. fewer locations with higher concentrations relative to lower concentration areas. In other words, one would not want to use the characterization survey data as the descriptive statistics for an area that has been cleaned up. Why are averages and variability important? Because the mean estimate of the contamination level in the remediated area and the uncertainty of that mean are the critical statistical inputs to the decision (DQO Step 3) for the remediated area's next phase, the final status survey (FSS).

Final status surveys

The final status survey is the only survey that is a requirement in impacted portions of the site, and FSS design constitutes the bulk of the MARSSIM guidance. The reason it is required is because the FSS generates the main data to demonstrate compliance with the cleanup objectives, and a comprehensive survey report is submitted to the regulator to support the site release request.

Overview of MARSSIM

The *Multi-Agency Radiation Survey and Site Investigation Manual* (NUREG-1575, Rev.1) was a multi-agency effort involving the NRC, EPA, DOE, and DOD. Their purpose was to develop an industry standard for how the FSS is performed and to ensure a consistent, integrated yet flexible approach, is applied when conducting radiological surveys. From the licensee's perspective, an important point is that MARSSIM-based final status surveys generally require fewer samples and/or measurements than past guidance. Fewer samples required for laboratory analysis results in considerable cost savings.

MARSSIM encourages the use of non-parametric statistics rather than parametric statistics. The non-parametric statistics are appropriate because they do not require the underlying assumption of a normal distribution that the parametric statistics require. This is important because of the population skewness expected due to areas of residual contamination.

Counter to the advantages, there are also limitations. MARSSIM's guidance does not include the assessment of subsurface soil contamination, or volumetrically contaminated structural components (e.g., walls). These matters must be addressed on a case-by-case basis. Also, MARSSIM's methodology for addressing localized areas of high contamination, or "hot spots," and other discrete particles of radioactive material (e.g., fragments of depleted uranium) is not particularly robust. Technology has also advanced since MARSSIM's inception and therefore the guidance does not address the use of modern computer-based instrumentation systems, e.g., systems that can simultaneously locate (i.e., scan) and quantify contamination, such as the GPS systems coupled to scanning equipment shown previously.

While MARSSIM's flexibility can be considered an advantage, the large number of decisions that the licensee must make can complicate matters. Like Newtonian physics, for every action there is an equal and opposite reaction. A change in one parameter will have other consequences, either negative or positive that must be understood. For example, taking fewer samples will reduce statistical power and thereby increase the probability of a Type II error. When taking advantage of MARSSIM's flexibility, the licensee must understand its methodology to avoid compromising the survey quality. Again, the use of the DQO process is necessary to ensure that the survey data will be of the right quantity and quality for decision making.

Design and implementation of the FSS

The site is first divided into discrete areas called survey units. The prior investigations are likely to have involved much larger and possibly less defined decision units. For the FSS, it is the survey unit that serves as the fundamental unit of compliance; every survey unit must be shown to meet the release criterion for the site to be released. Quite a bit of thought is required when subdividing the site into survey units. Different survey units at a site can differ in their radionuclides of concern, size, scan coverage, type and number of measurements, etc. but a given survey unit can only have a single classification (Class 1, Class 2, or Class 3) and its size is linked to its class. As indicated in Fig. 9, the greater the potential for contamination, the smaller the survey unit to ensure a reasonable sample density based on contamination potential.

Also, MARSSIM provides guidance on maximum allowable survey unit sizes for each classification that are shown in Table 4:

A sampling plan is prepared for each survey unit. The default sample plans are based on two non-parametric statistical tests, the Sign test and Wilcoxon Ranked Sum (WRS) test. The Sign test is a single sample test and is used when the contaminant is not present in background or, the $DCGL_W$ is well above background and thus background does not need to be accounted for. The test compares the median/mean (because it is non-parametric the test is actually comparing the median which is not affected by outliers) concentration in the survey unit to the $DCGL_W$ in order to determine whether the median concentration is less than the $DCGL_W$. The WRS test is a two sample test in which the survey unit median is compared to a background reference area, to determine if the median concentration is less than the background median plus the $DCGL_W$.

Both tests apply a hypothesis test. The assumed base condition is referred to as the null hypothesis (H_0). In the case of the FSS, the base condition assumes the survey unit is contaminated above the $DCGL_W$. This is written as:

$$H_0 = \text{median}_{\text{survey unit}} \geq DCGL_W$$

The alternative hypothesis (H_A) is that the survey unit median concentration is less than the $DCGL_W$ or:

Fig. 9 Illustration of MARSSIM survey unit sizes.

Table 4 MARSSIM recommended maximum survey unit size.

<i>Survey Unit Classification</i>	<i>Land Areas</i>	<i>Buildings (floor area)</i>
Class 1	2000 m ²	100 m ²
Class 2	10,000 m ²	1000 m ²
Class 3	no limit	no limit

$$H_A = \text{median}_{\text{survey unit}} < \text{DCGL}_W$$

It takes overwhelming evidence to reject H_0 and accept H_A . This is analogous to the legal system, except with the opposite presumption of guilt; the survey unit is assumed guilty until proven innocent rather than innocent until proven guilty. This is a very important distinction. Whichever condition has the most severe consequence if incorrectly rejected is set as the base condition. The erroneous release of contaminated survey unit is more severe than incorrectly deciding not to release a clean survey unit, hence the reason for establishing H_0 as assumed contaminated.

For both tests, the inputs required to determine sample size are the Type I (referred to as the regulator's error under the MARSSIM paradigm) and Type II error which is the site's error of concern. The other inputs are the DCGL_W , the lower bound of the gray region (LBGR)—normally established at the estimated mean concentration—and the variability in the survey unit. Those three factors are combined into an equation known as the relative shift.

$$\frac{\text{DCGL} - \text{LBGR}}{\sigma}$$

Once the relative shift is calculated, a table in MARSSIM can be consulted for number of survey unit samples needed. **Table 5** reproduces Table 5.5 of MARSSIM, used when the Sign test is planned. To illustrate, suppose the Type I error is selected at 0.05, equivalent to 95% confidence, and the Type II error is established at 10% which is equal to 90% power. Then, for plugging into the relative shift equation: an example DCGL_W of 1.0 is used (any units will do for the example), the LBGR is 0.5 and sigma is also 0.5 (both are in the same units as the DCGL_W):

$$\frac{1.0 - 0.5}{0.5} = 1$$

Looking up the relative shift and decision errors in the table is simple as shown in **Table 5** where the column corresponding to the decision errors intersects with the relative shift value. The answer: 23 samples are required to satisfy the planning inputs.

Further emphasizing the concepts introduced with **Fig. 4**, the closer (larger) the LBGR is to the DCGL_W and the larger the variability (σ) is, the smaller the relative shift becomes. Small relative shift values equate to larger required sample sizes to reject H_0 . Suppose now that both the LBGR and sigma were much larger, we will say 0.75 (meaning the average contamination level is much closer to the DCGL_W and there is much greater variability in the population), and the resulting relative shift equaled 0.3; then 185

Fig. 10 Example power curve (created using Visual Sample Plan, PNNL, 2019).

samples would be necessary to satisfy the desired confidence level and power. That number of samples would likely be unrealistic due to cost or other factors. This is where the Newtonian physics metaphor comes into play. One alternative to reduce sample size would be to adjust, decrease, the LBGR. However that increases the risk of failing to release a clean survey unit. The power curves shown in Figs. 11 and 12 show this relationship.

Power curves

VSP includes an interactive graphing capability to examine the impact on sample sizes and decision error probability. An example power curve is shown in Fig. 10 for a one-sample Sign test.

If unfamiliar with how to read a power curve, it essentially shows what mean concentration was input for the sample planning design. The LBGR was 0.5; the action threshold of 1 was selected; and the assumed standard deviation was 0.5. Note that the aforementioned input parameters are specified in terms of unity. The Type I error is 5% (0.05 on the Y-axis), which the curve crosses at the derived concentration guideline level (DCGL_W) of 1, and the Type II error is 10% (0.10), which occurs at the LBGR. Power is defined as $1 - \beta$, so where does one look on the curve to find power or the probability of making a correct decision?

The circled area of Fig. 11 shows if the mean/median of the survey unit was equal to $\frac{1}{2}$ the DCGL_W what the probability would be of correctly deciding that the survey unit is less than the DCGL_W. The Type II error, ($1 - 0.90$ in this case) is incorrectly deciding that the survey unit stated concentration is greater than the DCGL_W. The curve should go through the selected power, 90% in this example, at the LBGR. However, the power is actually higher than 90%, approximately 98%. Why is that? The higher power results from VSP increasing the sample size of 19 by 20% to $n = 23$ in accordance with MARSSIM guidance. Sample sizes are increased to maintain planned power should some samples either not be collected or the data are not useable due to quality control issues.

The curve is useful for examining planning error impact on desired power. What if the 0.5 mean (LBGR) is an underestimate? Suppose the mean is closer to 0.75? In that case, find where 0.75 on the X-axis intersects the curve on the Y-axis—shown on Fig. 11.

Based on the planned 23 samples, the probability of making the correct decision if the actual mean is 0.75 is only 58.3%. The VSP inputs can be toggled to determine how many samples are required to achieve 90% power at a mean of 0.75. The answer is 71.

Conversely, suppose the planning team had overestimated the mean at 0.75 by using judgmental sample data and the actual mean was 0.5. With 71 samples, the power curve would show $>90\%$ at 0.75 and essentially 100% power at 0.5, but at what cost? 48 more samples than necessary.

Fig. 11 Power illustration at a mean of 0.5 (created using Visual Sample Plan, PNNL, 2019).

Indistinguishable from background

Another alternative to the default MARSSIM methodology for determining whether site concentrations satisfy the DCGL_W is referred to as Indistinguishable from Background, or Scenario B. Scenario B is reserved for very specific situations where the ROC is also present in background, the DCGL_W is very low relative to background, and there is significant variability in background where it proves difficult for the statistical tests to distinguish contamination from what might only be higher background. The assumed Scenario B base condition is that the survey unit ROC concentrations are less than the DCGL_W . The null hypothesis is reversed, thereby easing the burden of proof that the site is clean as it will take overwhelming evidence to conclude the site is contaminated in excess of the DCGL_W . A complete description of the statistical methods used in Scenario B, in addition to the MARSSIM adopted statistical methods, may be found in NUREG-1505 (NRC, 1998).

FSS procedures

The FSS procedures are similar to the other surveys, consisting of radiological scans and direct measurements using appropriately sensitive alpha, beta, and gamma detectors and sampling. MARSSIM has specific requirements that must be met regarding scanning coverage and detection sensitivity.

Recall the discussion that MARSSIM introduced an integrated process. Scan coverage and required scan sensitivity demonstrate both the graded approach concept and how different procedures are integrated together to strengthen the confidence in the investigation. For the graded approach, the greatest effort is expended in areas with the highest residual contamination probability. In decreasing order of potential: Class 1, 2, and 3. In Class 1 areas, remediation is not necessarily precise. For instance while a trackhoe is excavating soil, all the contaminated soil may not be removed, or after loading into a truck material spills enroute to the waste handling area. Therefore, Class 1 survey units require 100% scanning coverage for the radiations of concern. Furthermore, the actual scan sensitivity, or minimum detectable concentration (MDC) must be demonstrated to be less than a required scan MDC. The applicable required scan MDC is a function on the allowable concentration in a hot spot of a predetermined size of concern. These allowable hot spot limits are referred to as DCGL_{EMC} ($\text{DCGL}_{\text{Elevated Measurement Comparison}}$). Smaller hot spots with higher concentrations can still satisfy the dose limit. However, for certain projects there are no allowances for hot spots that exceed the DCGL_W . In that case, the required scan MDC would be equivalent to the DCGL_W . Fig. 12A and B show the completed required scanning results as well as the planned sampling locations that resulted from the FSS DQO outputs.

Class 2 areas should not have any contamination in excess of the DCGL_W , and should not have required remediation. Had contamination above the DCGL_W been found either during an earlier survey or during the FSS, the survey unit would have required

Fig. 12 (A and B) Final status survey scan and sampling maps for the remediated soil area seen in Fig. 7A–C.

Fig. 13 3-D image of FSS alpha-plus-beta scan results.

reclassification to a Class 1. Class 2 FSS scan coverage requirements are 10 to 100%. Higher density scans occur in areas with the greatest probability of having become contaminated above the $DCGL_W$, such as where a Class 2 unit shares a boundary with Class 1 units or areas with the greatest potential for anthropogenic impact from radiological materials. Fig. 13 represents Class 2 scanning results. The data captured were from a former research reactor bay and spent fuel pool. The reactor bay was a Class 2 with approximately 25% coverage, the fuel pool was Class 1 and scanned 100%. The data show no residual contamination for the areas investigated.

Finally, because there should be very low potential for contamination in a properly classified Class 3 area, scan coverage requirements are minimal with judgmental scans recommended. That means scanning the areas that would be the most suspect locations to have possibly accumulated contamination.

Once scans are completed, judgmental samples are collected from suspect anomalies and random samples from each survey unit for laboratory analysis. The results are provided in units of the DCGL_Ws and the direct measurement results are converted to surface activity levels using appropriate detector efficiency and other conversion factors. Survey unit data are then assessed for compliance with the DCGL_Ws.

DQA

FSS data are compiled and evaluated. The scanning data are reviewed, plotted/mapped, and examined for anomalies. The judgmental data collected from anomalies are not included in the statistical assessment but are examined independently to ensure that the concentrations are below classification thresholds; a fraction of the DCGL_W for Class 3s and the Class 2 threshold is the DCGL_W. Hot spot samples that exceeded the DCGL_W from a Class 1 survey unit are assessed to ensure they were below the applicable DCGL_{EMC}.

The random sample evaluations include generating basic statistical parameters, graphing, or plotting of the data. The decision to perform the Sign or WRS test depends upon the initial assessment outcome. In many cases the initial review will show that either the survey unit will always pass the hypothesis test—the null hypothesis will always be rejected—while in other cases the survey unit concentrations will obviously fail the hypothesis test. Table 6 reproduces MARSSIM Table 8.2 hypothesis testing summary for when a survey unit would always fail, always pass, and when the statistical test is required to decide when the survey unit does or does not satisfy DCGL_W.

Refer to MARSSIM for examples of how the tests are performed.

Confirmatory/verification survey

The surveys presented thus far are performed by the site or their contractor, the regulatory authority also has a place in the RSSI phases. The regulator may conduct a verification survey, also referred to as a confirmatory survey, to collect independent data to substantiate and provide confidence in the reported FSS results. Verification activities that might be performed include performing independent scan surveys, measurements, and sampling. Data are tested for agreement with the site's results.

The RSSI process does not always proceed in this sequential flow. To a large extent, the radiation survey and site investigation process proceeds independently in different portions of the site. Additionally, all the surveys types discussed may not necessarily be performed in all areas. For instance, an area determined during characterization to not exceed the cleanup criteria is unlikely to be remediated, and therefore there would not be a need to perform a remedial action support survey. In one area of the site, only the FSS might be required. In other areas, the scoping, characterization, remedial action, and final status may all be necessary. There may be cases where one could go straight from the scoping survey to the FSS, such as an area that is clearly Class 3, or plan a scoping or characterization to also satisfy FSS requirements. After all, when the DQOs are planned correctly and appropriate survey methodologies implemented, a site may ensure that the quantity and quality of data collected are of the right type to satisfy multiple objectives.

Table 6 MARSSIM Table 8.2.

<i>For WRS test</i>	
<i>Survey result</i>	<i>Conclusion</i>
Difference between largest survey unit measurement and smallest reference area measurement is less than DCGL _W	Survey unit meets release criterion
Difference of survey unit average and reference area average is greater than DCGL _W	Survey unit does not meet release criterion
Difference between any survey unit measurement and any reference area measurement greater than DCGL _W and the difference of survey unit average and reference area average is less than DCGL _W	Conduct WRS test and elevated measurement comparison
For Sign test	
All measurements less than DCGL _W	Survey unit meets release criterion
Average greater than DCGL _W	Survey unit does not meet release criterion
Any measurement greater than DCGL _W and the average less than DCGL _W	Conduct Sign test and elevated measurement comparison

Introduction

This article is preceded by topics that are important to a discussion of radiation protection, but none is a protection, per se. That is, even the most thorough understanding of health effects, radiation detection systems, regulations, etc. will not protect people and the environment from the harmful effects of radiation unless that knowledge is used to design and implement appropriate radiological control practices. This article is an explanation of such practices.

The importance of planning

The National Institute for Occupational Safety and Health (NIOSH) has developed a “Hierarchy of Controls” that serves as a valuable planning tool for organizations seeking to reduce occupational injuries, illnesses, and fatalities. The hierarchy is presented in [Fig. 1 \(CDC, 2020\)](#). It is not explicitly a radiation protection; rather, it depicts an order of controls that can be implemented to curb exposures to any occupational hazard. Although the hierarchy was developed as a means of protecting workers, it reflects an approach that can be used to consider control solutions that also protect the public and the environment.

The premise underlying the hierarchy is that controls at the top of the figure are most effective and therefore more protective. Controls at the bottom are least effective and protective. Unfortunately, the controls at the top, eliminating the hazard or substituting it, may be impossible to implement, particularly at existing installations. For example, it is not feasible to eliminate or substitute radiation at a reactor site. Thus, the possible controls that remain are engineering controls, administrative controls, and personal protective equipment (PPE). This sequence of controls, starting with engineering controls and ending, as a last resort, with PPE, is preferred by virtually every safety organization in the world.

If the hierarchy is applied to radiation exposure in instances where the hazard cannot be eliminated or substituted, then ideally the hazard is controlled through facility and equipment design features such as ventilation, containment, shielding, and interlocks. Engineering controls of this nature are considered in the early planning stages of a facility, project, or process. When design features do not sufficiently mitigate radiation exposure, then administrative and procedural controls are planned. The takeaway then is that the most important factor in preventing harm from radiation must be planning. That is, exposures are kept low by incorporating radiological considerations well before the hazard presents itself rather than by reacting to whatever radiation arises from a given activity.

A special case for planning is needed when work such as maintenance, modification, or decommissioning is performed on or at a nuclear installation as these activities can temporarily or permanently suspend existing engineering or administrative controls ([DOE, 2008](#)). Moreover, these activities may create or exacerbate radiological hazards such that existing controls are not robust enough to adequately manage exposures. Consequently, an evaluation of the appropriateness of existing controls is warranted whenever non-routine work is performed.

Fig. 1 NIOSH hierarchy of controls. The National Institute for Occupational Safety and Health, www.cdc.gov/niosh/topics/hierarchy.

It could be argued that controls for emergency situations such as nuclear catastrophes are special cases that rely more on a strong reactionary response than design. Nonetheless, many elements of emergency response can and should be planned to increase the effectiveness of the response. Who will respond? What training will responders need, and is there a way to get them high quality training before the emergency arises? Who will be in charge of the response, and who will communicate to the public? What procedures and equipment will be needed, and is it possible to secure these items in advance? Can the facility design be amended in a manner that either prevents the emergency from occurring or mitigates its severity? It is impossible to plan for every element of every emergency, but emergency responses are more efficient when planning is leveraged to the extent practical.

Engineering controls

Engineering controls work by removing the hazard at the source or isolating people from the hazard (CDC, 2020). The most common engineering controls are shielding, containments, ventilation, and interlocks.

Shielding is accomplished with a physical barrier that blocks radiation. The barrier works because as radiation interacts with the shielding material, it loses some or all its energy. The radiation is said to be attenuated. The effectiveness of shielding is material-specific, and different materials are better suited for some radiations than others. Dense metals such as lead and steel are generally understood to be effective shields against photon radiations including X- and gamma rays. These same materials are ineffective for neutrons and high energy betas, as the former simply bounce off in another direction without losing much energy and the latter are stopped so fast that new photon radiation is emitted which must now be shielded. Neutrons are best shielded with hydrogenous materials such as water and concrete, and betas are effectively shielded with plastic, but photons are not stopped nearly as well by any of these materials. Lead, steel, water, concrete, and plastic will all stop alphas, but so will a standard thickness of paper; thus, complex alpha shields are difficult to justify.

Shielding is characterized as being permanently installed or temporary. A disadvantage of temporary shielding is that it is generally the more mobile of the two types, and if it is inadvertently moved could result in less protection than anticipated. As the nomenclature suggests, temporary shielding is intended to be a used as a temporary control during infrequent or irregular activities, and sites should not rely on temporary shielding as a long-term fix for poor permanent designs that fail to control exposures during routine or recurring activities.

Containments are used when handling hazardous quantities of unsealed radioactive material. They rely on physical barriers to keep contamination from spreading to uncontrolled areas. Containments may be constructed from durable materials, as in the case of permanently installed concrete, steel, or gypsum walls, but temporary containments such as gloveboxes and a variety of flexible enclosures including tents, bags, and catch containments are also popular. In some cases, a series of containments are used. Radioactive material is used within a "primary" containment that provides the main protection, and a "secondary" containment surrounds the primary containment in case the main protection fails or is otherwise breached.

Ventilation removes air from a space and thus any entrained radioactive particles the air contains. In turn, those particles are not present to be inhaled or ingested or to settle out as dust and buildup to hazardous concentrations over time. Ventilation is often used in conjunction with containment, and a fume hood is an example of a control that relies on a combination of containment and ventilation. Ventilation is used with installed filtration that is suitable to the contaminants being exhausted. For example, High

Efficiency Particulate Air (HEPA) filtration is used to remove radioactive airborne particulates but is not effective for radioactive noble gasses.

Interlocks prevent areas from being entered when hazardous levels of radiation may be present. For example, an interlock could cause doors to remain locked when a radiation-producing machine is on but allow the doors to unlock when the machine is switched off. Similarly, an interlock could prevent a machine from starting while a door is open.

Administrative controls

Administrative controls change the way people work (CDC, 2020). The number of important administrative controls is vast, but critical examples include written operating procedures, access controls, surveys and monitoring, decontamination, and waste management. These controls are explained in the following paragraphs.

Procedures

Once a site is designed, planning for operations, maintenance, and modifications begins with development of site-specific operating and radiation safety procedures. These documents describe programmatic elements and serve as formal administrative controls that convey and promote consistent radiation safety practices. In a broad sense, the radiation protection procedures at a nuclear facility will cover topics including program and organizational structure; training and qualification; surveys and monitoring; exposure, contamination, and airborne radioactivity controls; waste management; receipt, storage, and control of radioactive material; emergency preparedness; and recordkeeping, but this list is not entirely inclusive. The procedure list will vary from facility to facility based on site-specific factors.

The first step in developing appropriate procedures is to identify the applicable regulatory requirements for radiation protection and associated standards and guidance documents. For example, the regulatory requirements for a US Department of Energy site differ from the requirements for a US Nuclear Regulatory Commission licensee, so the respective radiation protection programs and corresponding manuals and procedures will differ.

Procedures should not just restate, paraphrase, or cite regulatory requirements and related documents. Rather, they should convey site-specific policies, programs, and instructions that are necessary to ensure compliance with the related regulatory requirements. Because site-specific procedures are better suited to provide protection than a generic approach, each site should have its own radiation protection manual and procedures rather than adopting the procedures used by others.

Access controls

Access is controlled with a variety of tools. Functionally, the number or physical accesses to and from an area containing radioactive material is limited. The limitation can be accomplished by rule or procedure, but barriers are ideal. Robust structural walls provide the best barriers, but poly containments and ropes on stanchions are popular. Painted or taped lines may be used to bound areas where controls apply, but such designations are not as effective as physical barriers that must be moved to gain access. Fig. 2 shows how tape may be used to denote boundaries where control is needed.

As few openings as possible are allowed through the barrier for egress, with consideration given to work efficiency and emergency exit and response, as fewer access points means fewer travel routes for contaminants to be unknowingly spread to other areas and better control, tracking, and monitoring of personnel entering and exiting radiological areas.

Rope barriers are commonly constructed of yellow and magenta twisted polypropylene as this combination is generally recognized as designating an area that is controlled for radiological purposes. Although these ropes are often a sure sign that an area is

Fig. 2 Example taped boundary. Courtesy Ameriphsysics, LLC.

under radiological control, this is not always the case. Other color combinations and materials are also used, a rope's colors are subject to fade over time, and the color combination tells potential entrants nothing about the severity of the hazard within. Consequently, postings and signs are used to convey instructions that are important to entrants.

The most common postings use nomenclature that signifies the magnitude of the risk presented by entry. For example, facilities operated according to US Nuclear Regulatory Commission rules categorize their work areas according to the degree of control that is warranted. At such facilities, a "restricted area" is any area to which access is limited for the purpose of protecting individuals against undue risks from radiation and radioactive materials, a "controlled area" is an area outside of a restricted area which can be limited for any reason, and an "unrestricted area" is an area to which access is neither limited nor controlled (NRC, 1991). Restricted areas are further categorized a radiation areas, high radiation areas, or airborne radioactivity areas according to the radiological hazard they present. US Department of Energy uses slightly different nomenclature than what is described here and as follows, but it is similar in that areas are named according to a graded approach that considers dose or contamination potential.

According to US Nuclear Regulatory Commission rules for restricted areas, a "radiation area" is an accessible area in which radiation levels could result in an individual receiving a dose equivalent in excess of 0.05 mSv in 1 h at 30 cm from the radiation source or from any surface that the radiation penetrates. A "high radiation area" is similar, except that an individual could receive a dose equivalent in excess of 1 mSv. A "very high radiation area" is an accessible area in which radiation levels from radiation sources external to the body could result in an individual receiving an absorbed dose in excess of 5 Gy in 1 h at 1 m from a radiation source or 1 m from any surface that the radiation penetrates. Finally, an "airborne radioactivity area" means a room, enclosure, or area in which airborne radioactive materials exist in concentrations that approach or exceed certain constraints on such radioactivity.

Radiation, high radiation, very high radiation, and airborne radioactivity areas are required by US Nuclear Regulatory Commission regulations to be posted. The typical posting is comprised of a sign bearing a magenta, or purple, or black three-bladed standard radiation symbol on yellow background and the words, CAUTION, RADIATION AREA; CAUTION or DANGER, HIGH RADIATION AREA; GRAVE DANGER, VERY HIGH RADIATION AREA; or CAUTION or DANGER, AIRBORNE RADIOACTIVITY AREA, as appropriate. Rooms in which licensed material is used or stored are required to be posted with the radiation symbol and the words CAUTION or DANGER, RADIOACTIVE MATERIAL(S).

Fig. 3 shows a typical posting—in this instance a high radiation area. Persons who understand what a high radiation area is are warned of the hazard potential simply by reading the sign, however, anyone recognizing the familiar standard radiation symbol is warned that a radiological hazard is present. For this latter reason, it is common to see postings displaying the radiation symbol used even when not required, such as in controlled areas and restricted areas presenting a dose equivalent less than the defining criteria for radiation areas.

Postings are purposely displayed in conspicuous locations, and the sign bearing the posting is often used to convey additional information regarding controls. Statements such as "no eating, drinking, smoking, or wearing of cosmetics", "dosimetry required for entry", "not an entrance", "contact radiation protection office for entry", and "radiation work permit required for entry" are often used even though not required by regulation.

Although postings convey important access-limiting information to entrants, space limitations restrict such information to concise statements or conclusions that may be inferred by area nomenclature. A radiation work permit, or RWP, is an additional access control that conveys details regarding the requirements for entry. For example, suppose a posted radiation area will be entered by two groups of workers, and one will conduct routine site visual inspections while the other will open potentially contaminated liquid systems for maintenance. The first group may be required to wear dosimetry but could potentially traverse the area without extensive PPE, monitoring, or contamination control training. The second group may require respiratory protective equipment, waterproof coveralls, continuous air and contamination monitoring, and specialized training. As the task-specific controls are too lengthy to attach to a sign, a separate RWP is issued to each group of workers for entries into the same posted radiation area.

Fig. 3 Example posting bearing the radiation symbol. Courtesy Ameriphsysics, LLC.

In addition to being task-specific, RWPs are site-specific. That is, the format and content of such will vary from site to site. Nonetheless, certain common elements are typical of RWPs. First, the content, format, issuance, and usage of the RWP will be described in an administrative procedure. Regarding content, most RWPs will contain space to record expected radiological conditions, such as general area and maximum radiation, contamination, and airborne concentration levels; required PPE; and monitoring requirements. RWPs are approved and rescinded according to a formal process, and the signatures for such are usually located on the form. Finally, anyone entering an area is expected to be briefed on the requirements for entry, so RWPs will contain space for recording that a briefing was held and for entrants to acknowledge by signature that they have attended the brief and have read, understand, and will comply with the requirements for performing work according to the RWP. Fig. 4 shows an example RWP format.

It has already been mentioned that the number of accesses to and from restricted areas are limited, and another common administrative control is to establish an “access control point” at such locations. A control point provides a central location to maintain applicable RWPs, a log of entrants and the time entering and exiting the area, a station for storing, donning, and doffing PPE, and

equipment for personal monitoring. Access control points are often assigned an attendant who verifies controls, particularly in cases where radiological conditions present a substantive risk.

Surveys and monitoring

Radiological surveys are conducted to comply with regulations, but also as a necessary control to evaluate the magnitude and extent of radiation levels, concentrations or quantities of residual radioactivity, and the potential radiological hazards (NRC, 1991). Radiation and contamination surveys are used to locate radiation sources and quantify dose rate, surface contamination, and atmospheric contamination, but the real benefit of surveys as a control is when they are used to identify changing conditions. That is, an area may be surveyed upon initial entry or before work begins, and then routinely thereafter to determine if operations are causing radiation or residual radioactivity levels to increase or decrease. Surveys are also valuable for identifying areas to be avoided and areas that may be cleaned to reduce exposure. Surveys at control points and other boundaries are valuable for verifying that contamination controls are working, and surveys of personnel and equipment that exit restricted ensure that contamination is not spread elsewhere.

When surveys are performed to verify the effectiveness of containment, contamination limits provide action levels at which an intervention such as decontamination is required to ensure continued control. Surface contamination limits designate acceptable levels of fixed or removable radioactivity, where fixed contamination is tightly adhered to a surface and removable contamination is loose and easily transferred or dispersed. When fixed and removable contamination are measured together, the nomenclature total contamination is used.

Just as surface contamination limits apply to surfaces, airborne contamination limits are used to signify when airborne concentrations are high enough to justify action. The action could be as simple as ventilating or cleaning the space, or as serious as vacating the area or donning respiratory protective equipment.

Personal monitoring is accomplished with survey meters as individuals exit restricted areas to ensure they are not contaminated, with dosimetry to track external dose, and with in vivo and in vitro bioassay to determine internal dose. The term “frisking” is used to describe the process wherein radiation detectors are passed slowly and as close as possible to a person’s body.

The equipment used for surveys and monitoring must be calibrated and in proper working order. Calibration is the checking of the values obtained by a measuring device against known values. In the case of radiation detectors, it is accomplished by measuring the emissions from calibration standards of known radioactivity. The frequency of calibration is a site-specific decision, but an interval not exceeding 1 year is typical. Calibrations for radiation detectors must take into account the energy of the radiation that will be measured. Some detectors are impacted by pressure and temperature, and these factors must be considered when using instruments in environments that differ from the calibration environment, such as when instruments are calibrated near sea level and used at higher elevations.

Calibrations are critical, but calibration by itself is not sufficient to ensure that radiation detection equipment is working properly. The equipment must also be checked regularly prior to use. Typical checks include examining physical integrity, checking batteries, and ensuring that values received when measuring background and a source of known activity are in expected ranges.

Decontamination

Operations may cause small amounts of residual radioactivity to build over time, or maintenance, leaks, or emergencies may result in significant short-term releases of radioactive material. Decontamination is the process wherein some sort of cleaning or remediation effort is conducted to return contamination to acceptable levels. Because decontamination concentrates contaminants onto towels, mops, filters, or other items used in the cleanup, containment of these items and control according to a waste management program are important.

Waste management

Radioactive waste can be collected, chemically and physically altered in form, packaged, and stored, but the radioactivity making the waste hazardous does not become inert via these processes. Since we cannot make radioactivity go away, we must wait for it to decay. For very long-lived radionuclides, this can take millions or billions of years, so it is important that management approaches are planned to protect present and future generations. Consequently, long-lived radioactive waste is usually transferred to specialty facilities that are designed to provide for long-term management. When containers are used to confine waste, the design of such packages must consider situations that might be encountered during transportation and disposal including traffic accidents, emergency braking, rain, etc.

Landfill burial is usually considered the practical endpoint of a waste management program. Engineering controls such as landfill liners and caps, and administrative controls such as site selection, permits, procedures, and monitoring are used to mitigate the hazard presented by the waste the landfills contain. In the end, however, burial is a specialized means of storage rather than a solution. That is, although radioactive wastes can be safely stored in these landfills for generations, the radioactivity still exists, and the public would be better served if the waste had not been generated at all. Consequently, waste minimization is a critical element of any management program as preventing a waste from being generated at its origin is the only completely hazard-mitigating control.

Exposure controls

When radioactivity presents an external hazard, radiation protection is accomplished with practices that control time, distance, and shielding (Cember and Johnson, 2009; Gollnick, 2011). Collectively, these practices are called “exposure controls”. In simple terms, exposure is minimized when time is also minimized and distance and shielding are maximized.

Time

The hazard presented by an exposure of a constant intensity is directly related to the duration of the exposure, meaning that if the time spent near a source presenting an external exposure is halved, the total exposure and corresponding risk are also halved. Similarly, if the time is doubled, the total exposure and risk are doubled. The manner in which exposure and time are related is easy to conceptualize, making practices that aim to minimize time practical exposure controls. Typical controls include prohibiting loitering near radioactive material and making sure workers understand and have practiced the work to be done (e.g., with mockups).

Distance

Imagine a baseball-sized mass of material that uniformly emanates gamma radiation in all directions. A person standing very near that source, just a few centimeters away, will be traversed by many of the gamma rays as they escape the surface, whereas few rays would point to and interact with a person standing across the room and away from the source. A simplification of the relationship between exposure and distance is that exposure is inversely proportional to the square of the distance of separation. Thus, if distance is doubled, then the exposure decreases to one-fourth of its original value. For example, if the previously described baseball-size source is delivering an effective dose 4 mSv per hour to a person working 1 m away, that person can reduce the dose rate of the field they are working in to 1 mSv per hour by doubling their distance—or working 2 m away from the source instead of one.

The extent to which this inverse-squared relationship is applicable depends on the geometry of the source relative to the distance at which the exposure occurs. Generally, the relationship works when the exposure distance is at least three times the largest dimension of the source and the source can be treated geometrically as a point source (Gollnick, 2011). Long-handled and remote-operated tools are a means of maximizing distance. Such tools allow workers to distance themselves from radioactive work surfaces that present a concern.

Shielding

Relying on the baseball-sized mass as an example again, a shielding material could be placed between a person and the source to shield the person from the gamma radiation emitted. If the gamma rays interact with the shielding in a manner in which all of their energy is lost, then they are prevented from interacting with and causing harm to the person. Similarly, if the gamma emissions are only partially blocked, then the person is exposed to the rays that penetrate the shielding.

Alphas and betas are charged particles and thus have predictable, finite ranges they can travel through shielding. This means that charged particles can be completely shielded. For radiations not characterized as charged particles, such as x-rays, gamma-rays, and neutrons, the amount of shielding needed to reduce an exposure is calculated with the concepts of half-value layer (HVL) and tenth-value layer (TVL). As the names suggest, each corresponds to the thickness of the layer needed to reduce the intensity to one-half or one-tenth of the original exposure, respectively. As an example, if a beam of gamma radiation is aimed at a shield twice as thick as the TVL, a beam 10% of the original intensity (one-tenth of 100%) will penetrate the first half of the shield, and a beam of 1% of the original intensity (one-tenth of 10%) will survive the entire shield thickness. Note that no matter how many HVLs or TVLs are used, mathematically the number of penetrating emissions is never reduced to zero. Nonetheless, a shielding thickness of 10 TVLs will reduce even deadly amounts of radiation to inconsequential levels, and five to seven TVLs are protective in all except the most extreme instances.

HVLs and TVLs vary numerically based on the composition of the shielding material and the type and energy of radiation involved. Once the value reflecting an HVL or TVL is known, however, that thickness works the same whether the shielding is placed close to or away from the source. From a design standpoint, this means that placing the shielding as close to the source as possible is often the best practical solution. As an example, consider the feasibility of building a two-inch thick lead box to contain a baseball-sized radioactive mass versus the complexity of surrounding the entirety of the same source by a room equipped with two-inches of lead on all its walls, floor, and ceiling when both designs accomplish the exactly the same amount of shielding and protection. On the other hand, if a room contains a thousand of such sources, shielding the room or using a combination of source and room shielding becomes reasonable.

Contamination controls

Unlike exposure controls that are concerned with external radiation, contamination controls are used to mitigate the internal hazard presented by radioactive material that is deposited on or within the body. In terms of possible harms, dose is dose, meaning the

effective dose from internally deposited radioactivity does not present an inherently different risk than the same amount of external dose. Whereas external dose quits accumulating as soon as the area containing the source is exited; however, internally deposited radioactivity will continue to deliver a dose as long as it is in the body, and in some instances this can be long after the exposed person vacates the area originally presenting the hazard.

Contamination controls are designed to prevent contaminants from entering the body through three pathways: inhalation, ingestion, and absorption through the skin (Cember and Johnson, 2009). This is accomplished by engineering and administrative controls that confine and enclose the source or PPE such as anti-contamination clothing and respirators that provide a barrier between the exposed person and the contamination (Cember and Johnson, 2009).

Confinement

Confining the source begins with designating areas for handling radioactivity, particularly unsealed sources. The buildings and rooms in which radioactive materials are used, including the ventilation, drains, and emergency systems they contain, are designed in a manner that leverages engineering controls to keep contamination contained during normal operations and certain emergencies. But confinement goes a step farther than designing and designating rooms; smaller areas within rooms such as hoods, certain bench tops, or other precise locations are further designated that can be equipped with contamination-limiting controls. For example, if the material presents a potential for emitting radioactive fumes, filtered ventilation may be situated near the release point rather than relying on the normally located room exhausts. Previously described containments and trays and pads that are used to cover benchtops are other sources of confinement that can be used within rooms.

When materials are used in the practice of confinement, such as in the cases of ventilation filters, portable containments, and pads, they are expected to become contaminated because of their use. Repair, replacement, cleaning, or maintenance involving such items presents a special case for containment as their mishandling may cause accumulated contamination to be released. Depending on the manner and concentration of the release, the resulting exposure may far exceed the dose that the confinement was designed to avoid.

Personal protective equipment

No containment system is 100% effective all the time, and even the most robust engineering controls are subject to failure. Consequently, PPE is worn when handling contaminated materials, when working in contaminated and airborne radioactivity areas, and as otherwise directed by the radiological control organization or as required by an RWP. Note that as described at the onset of this article, PPE is considered the least effective of the three types of control measures and thus is not a suitable substitute for proper planning that confines the hazard with engineering and administrative controls.

The term PPE is used to describe any equipment that is worn by an individual to prevent exposure to workplace hazards. In the usual sense where radioactivity is a concern, PPE is used to prevent contamination of a person's skin or clothing or inhalation or ingestion of radioactive material. That is, PPE is not usually worn as a radiation shield, except that lead aprons are sometimes used in the presence of X- and gamma-radiation and plastic eyewear is an effective shield against beta radiation to the eyes.

The simplest PPE ensemble that is protective against radioactive contamination consists of a water-repellent gown or coveralls, safety glasses or goggles, surgical-style gloves, and shoe covers. The coveralls may be equipped with a hood or used with cap, and the gloves and shoe covers are often taped to the coveralls. Protective clothing can be reusable or disposable, and the former is laundered at facilities specially designed to collect and manage radioactivity in wash water.

Respirators are a special type of PPE that control internal exposure by limiting the intake of radioactive material via inhalation or ingestion. Numerous respirator types operate via a variety of operating modes, and each combination is associated with a performance characteristic called protection factor. In order of increasing protection factor, respirators are generally categorized as being air purifying, atmosphere supplying, or self-contained breathing apparatus (SCBA). Because air purifying respirators rely on filtration, they are only effective where airborne contaminants present in a particulate form. Atmosphere-supplying respirators and SCBA are protective against particulates but are also effective when the contaminant is a gas or a vapor. Misuse of respirators or their mechanical failure during use could expose workers to contaminated atmospheres in a manner leading to dire consequences. Consequently, respirator use is accomplished according to robust respiratory protection programs that include controls such as training, maintenance, and inspection requirements.

Assigning respiratory protective equipment is not a control decision that is taken lightly. Respirators make work harder, and they make it difficult to see and breathe. As such, respirators are only assigned to persons who have been medically cleared and trained on the respirators they will be using. Because the respirator only works if it fits and seals properly, wearers are also required to receive and pass a fit test with the exact respirator type and size that they will be using.

Just as a containments become contaminated through their use, PPE is expected to become contaminated as it is used. Wearers must be careful not to contaminate themselves when they are removing such clothing, and collecting and managing the waste presented by used PPE is important.

Optimization

In the end, the best radiation protection programs are site-specific and rely on a combination of the engineering, administrative, and PPE controls described herein. The fact that such controls are planned and used, however, does not mean they are working in an optimal manner. Moreover, the implementation of controls aimed at mitigating radiological risks may cause or exacerbate other hazards as discussed in the article on risk tradeoff. Consequently, performance assessment is used to verify that controls are operating as expected and to seek opportunities for improvement. The Integrated Safety Management platform US Department of Energy uses to integrate safety into management and work practices at all levels is an example of an assessment process that invokes principles of continuous improvement.

Assessment is accomplished with formal surveillance programs that observe people and their environments with techniques aimed at determining the effectiveness of controls. Because a key objective of performance assessment is continuous improvement, surveillance programs are designed to regularly reexamine performance. Finally, such surveillances are expected to return findings and offer recommendations. That is, assessments that always show perfect performance should be considered evidence of an underperforming surveillance program rather than of perfectly optimized and executed radiological controls.

Introduction

The world is now full of sources of radiation, both man-made and natural; many of them are purposefully created for medical, energy, national defense, and industrial uses. The field of radiation shielding involves the protection of people (and, to a lesser extent, equipment) from the danger posed by the deposited energy of this radiation.

The need for shielding arises because radiation energy that is produced in one place is deposited at distant points, with the distances involved proportional to distances at a human scale. Some radiation particles (e.g., low-energy alpha particles) deposit their energy so close to their point of creation that there is no need for shielding from an external source beyond a piece of paper to protect personnel (although ingestion and inhalation can cause damage); others (for example neutrinos) deposit their energy so far from their point of origin that it is futile to try to protect personnel from them.

The primary need for shielding on the Earth's surface arises for protection from uncharged particles, primarily neutrons and gamma rays (although some high-energy electrons need direct shielding as well). But the primary task for shield designers is concentrated on uncharged particles that have average traveling distances between interactions with material (referred to as *mean free paths*) in the range of centimeters to meters. The scale of these mean free paths make it both necessary and effective to create material shields for protection of nearby personnel.

The physical reason why neutral particles travel so much farther than charged particles is that the neutral particles have to directly impact the sparse nuclei in materials through which they pass in order to interact with them, whereas charged particles electrically interact with the electrons and protons in atoms near their path, in the process depositing their energy in a far shorter distance. Charged particles also collide with the atoms of the materials through which they pass, but this is a much less significant source of energy deposition.

So we will concentrate our attention on the methods that have proven themselves useful in predicting the damage caused by neutrons and photons. Shielding against high energy charged particles is discussed by (Heilbronn, 2021).

Basic principle of radiation shielding: Conversion of particle flux to dose rate

The actual damage to biological tissue is produced by the deposited energy of the short-range charged particles that are created when neutrons or photons interact with matter. These secondary particles are not as penetrating as the neutral particles that produced

them, but they cause far more damage to living structures because their energy is deposited in a concentrated manner, over a short distance (often just a single or a few biological cells).

Although the purpose of radiation transport calculations is to predict biological effects (or other physical properties), we get to that goal by the calculation of *particle flux* (denoted by the Greek symbol ϕ), which is defined as particle density (particles/unit volume) times velocity (distance travelled/unit time), resulting in a measure of the particle path length per unit volume per unit time; this results in flux units of particles/unit area/unit time, usually expressed in units of particles/cm²/sec.

This flux is then translated into a biological effect by multiplying by a factor that is generically referred to as a *response function*; particular response functions are deduced from physical or biological experimental data. This approach works both for determining rates (e.g., dose per unit time) and for the accumulation of effect over time (total dose), depending on whether the particle source rate is given in source rate (particles/unit time) or total particles released during a limit-time event (like a burst). In the latter case, the flux would not be a time rate, and is referred to as a *fluence* with units of total particles/unit area (usually particles/cm²).

The resulting dose rates are usually expressed in either units of sieverts (Sv) or the older unit of *rems*; there are 100 rems in a sievert. For photon dose, a sievert corresponds to the biological effect of a deposited energy of a *gray* (Gy), defined as the deposition of 1 J/kg of tissue. For neutrons, the conversion rate from gray to sievert is usually greater than one (referred to as a relative biological effectiveness) due to the greater biological damage caused by charged particles produced by neutron interactions with the tissue nuclei.

Basic tools of radiation protection: Time, distance, shielding

There are three primary defense mechanisms that protect people from radiation: time, distance, and shielding.

Time

The first of the defense mechanisms is time. In most cases (burst-type accidents being the primary exception), a neutron source or photon source consists of radioactive material that emits particles at a rate that decreases as the radioactive source material decays. This source rate produces a dose rate, e.g., in units of Sv/sec. Since our goal is the reduce dose (in Sv) received by personnel, the first defense from the radiation is to minimize the time spent in places with high dose rates.

In a typical shielding analysis, the analyst would produce a map of dose rates by position and this would be combined with occupancy information for both radiation workers and the public to determine expected total doses received by personnel.

Distance

The second defense mechanism is distance. In an idealized situation, a source that emits all of its particles from a single point, equally in all directions, at a constant rate of S particles/sec would—in the absence of any shielding—produce a dose rate that decreases as a factor of distance squared. This can be easily deduced from the fact that at a distance of r cm from the source point, the spreading particles would be evenly distributed on the surface of a hypothetical sphere of area $4\pi r^2$ (with the source point at the center of the sphere.)

For example, in the idealized situation where a million particles/second are being emitted from a given point source, the flux at a distance of 50 cm from the point would be the emitted particles spread out over the area of a sphere of radius 50 cm, resulting in a flux given by:

$$\phi = \frac{10^6 \text{ particles/second}}{4\pi(50 \text{ cm})^2} = 31.83 \text{ particles/cm}^2/\text{sec}$$

If the million particles per second being emitted are photons with an energy of 2 MeV (MeV), using the data presented later (in **Table 1**) gives us a dose rate of:

$$\begin{aligned} \text{Dose rate} \equiv D &= R\phi = (7.45 \times 10^{-12} \text{ Sv} \cdot \text{cm}^2) \times (31.83 \text{ photons/cm}^2/\text{sec}) \\ &= 2.37 \times 10^{-10} \text{ Sv/sec} \end{aligned}$$

At first glance this seems like a very small dose rate, until you realize that Sv is a relatively large dose unit and second is a very short period of time; in the United States, radiation dose limits are usually expressed in mrem/year. Since a rem is 0.01 Sv and the typical work year is 2000 hr, the dose rate would translate into:

$$\begin{aligned} \text{Dose rate} &\equiv 2.37 \times 10^{-10} \text{ Sv/sec} \times \frac{100 \text{ rem}}{1 \text{ Sv}} \times \frac{1000 \text{ mrem}}{1 \text{ rem}} \times \frac{3600 \text{ sec}}{1 \text{ hr}} \times \frac{2000 \text{ hr}}{1 \text{ year}} \\ &= 171 \text{ mrem/year} \end{aligned}$$

A person exposed to this dose rate for a full year would receive a bit more than half of the average annual dose rate in the U.S. from environmental radiation sources of 310 mrem/year (Wahl, 2010).

10	23.0	0.0532	0.236	0.564

Data derived from Shultis and Faw (2000).

Shielding

The third defense mechanism is the placement of shielding material of some sort between the particle sources and the places that need to be protected. Predicting the effect of such shielding can be very complex because of the different physical consequences of radiation interacting with material. For example:

- The particle can be absorbed, thus providing loss of the particle;
- The particle can scatter off the material nuclei, changing direction and energy; and
- The particle can interact with an atom of the shield material and generate more particles of the same or different types.

The complex combination of space, direction, and energy effects of particle interaction with the shield material makes the determination of the resulting dose rate maps more complex than the simple consideration of source rate and distance. Of special concern are the dose rates from neutron sources, because allowance must be made for the photons that are produced by neutrons undergoing scattering and neutron absorption. This generally means that complicated computer codes need to be utilized to get accurate dose rate maps.

It is possible to use more approximate methods to check the reasonableness of the more complex computer analyses or even (for simple geometries) to get answers for which a safety factor can be utilized to get satisfactory results for design purposes.

Result: Dose rate map

A typical result of a shielding analysis is an area dose map, which gives a graphical representation of how the dose rate varies by space—at a given elevation (e.g., 100 cm above the floor for personnel working on the same level as the source). Careful attention to the dose maps will reveal the effects of distance, shielding, and the effect of particles reflecting off of the floor, ceiling, and walls.

Hand calculations of spatial dose rates

Hand calculations can be effective in determining the dose effect of shielding in simple arrangements and in estimating the dose rate in more complicated geometries as a check of the results from more accurate methods.

We shall focus on a simplified situation, often encountered in practice, of a shield of a known material and thickness from a small source, approximated by assuming the source particles are emitted from a single point.

Uncollided dose rate

The first approach is to determine the dose impact of the original particles emitted from the source, ignoring the contribution of particles that have scattered or have been produced from particle reactions. In effect it is what the dose rates would be if particles interacting with nuclei in the shields were always absorbed. This is the portion of the dose rate produced by original source particles that have passed through the shield without colliding with any of the atoms in the shield.

The uncollided dose rate, due to both distance attenuation and shielding attenuation of a source of energy E , can be very easily shown to follow the relation:

$$D_0(r, E) = \frac{S_p R(E)}{4\pi r^2} e^{-\mu(E)t}$$

where: S_p is the source intensity in particles/second of energy E ; $R(E)$ is the flux-to-dose conversion factor in $\text{Sv}\cdot\text{cm}^2$ for particles of energy E ; r is the distance between the source and the dose point in cm; t is the straight-line thickness of shielding material between the source and the dose point in cm; $\mu(E)$ is the linear attenuation coefficient for particle of energy E in the shielding material in cm^{-1} ; and $D_0(r, E)$ is the resulting dose rate due to the original uncollided source particles of energy E in Sv/second .

Typical values for $\mu(E)$ and $D_0(r, E)$ is provided in (Shultis and Faw, 2000) and (ENDF Data—T-2). A subset of these data is given in Table 1 for photons and Table 2 for neutrons. These data clearly illustrate how the interaction coefficient decreases with particle energy (i.e., higher energy particles are much more penetrating).

Buildup of scattered photons

Calculating the dose contribution of the particles that come directly from the source is straightforward because the dose reduction depends only on the straight-line path between the source and the dose point. Accounting for the contribution to the dose of source particles that are scattered from the shield nuclei or that are created from other particles emitted as a result of the original particle reactions (like the photons produced from neutron absorption and inelastic scatter) is more complicated.

For the case in which the intervening material is a single homogeneous material—often a good approximation of shielding situations—some rough accounting for the effects of scattered photons can be made through the use of *buildup factors*. These are tabulations (or function fits) of the ratio of the total dose to the uncollided dose as a function of initial particle energy and uncollided attenuation of the intervening shielding. A common way of accounting for this buildup is to use the two parameter Taylor formula, given by:

$$B(E_0, \mu(E_0)t) = A_1 e^{-\alpha_1 \mu(E_0)t} + A_2 e^{-\alpha_2 \mu(E_0)t}$$

where: $B(E_0, \mu(E_0)t)$ is the buildup factor; E_0 is the initial energy of the emitted photons; $\mu(E_0)t$ is the linear attenuation factor times straight-line shielding distance (i.e., the same factor used in the exponential term of the uncollided dose rate calculation); A_1, α_1, α_2 are source-energy-dependent parameters; $A_2 = 1 - A_1$ (to preserve the initial value $B(E_0, 0) = 1$).

Notice the difference between r (the total distance from the source to the desired dose point) and t (the portion of this distance corresponding to the shielding).

Typical values for the parameters of the equation are provided in (Shultis and Faw, 2000). A subset of these data is given in Table 3.

The resulting determination of the total dose is then found from the relation:

$$D_{\text{Total}}(r, E) = D_0(r, E)B(E_0, \mu(E_0)t)$$

Tenth value thicknesses for neutrons

For neutrons, the same equation for the uncollided dose contribution can be used (with appropriate values of the linear attenuation coefficients and flux-to-dose conversion factors), although accounting for the dose contribution of scattered neutrons is usually more difficult than for photons. One common technique for approximating neutron and photon dose rate reduction through shielding is to specify *tenth value thicknesses*—corresponding to the shield thickness of a given shielding material and particle source energy that would produce a total dose reduction of a factor of ten; these tenth value thicknesses can be determined either experimentally or through computer calculations. Table 4 gives the tenth value thicknesses for several materials for both neutrons and photons; these were determined from the most conservative (highest) asymptotic dose reduction factors over a range of particle energies from 0.01 to 10 MeV. Of particular note is how effective iron and lead are for shielding from photons. (The corresponding

Data taken from Shultis and Faw (2000).

Table 4 Tenth value thickness for various materials.

Material	Tenth value thickness (cm)	
	Neutron	Photon
Concrete (regular)	28	52
Iron	63	11
Lead	81	5
Water	49	141
Polyethylene	53	167
Polyethylene with 5 wt% B ₄ C	40	142

half value thicknesses—the approximate shield thickness that reduces the dose rate by a factor of two—can be found by multiplying the tenth value thicknesses in the table by $\log_{10}(2)$, which is about 0.3010.)

It should be noted that the tenth value thicknesses are asymptotic values; that is, they are more useful for estimating the effect of adding shield material onto an existing shield than they are for determining the effect of the initial shielding layers. As will be shown in “Sample Problem #2” section (see Fig. 4), dose rate in the shield does not reduce proportional to the tenth value thickness until the shield has significant thickness.

Room reflection

The preceding results—both photon buildup factors and neutron/photon tenth value thicknesses—are based on the common situation in which the shield provides complete protection between the particle source and the detector point (i.e., no particles can scatter around corners or through holes in the shielding).

But for situations in which the particles can find other paths to the desired dose point—doors, equipment or ventilation ducts, serpentine shielding designs, etc.—a significant dose contribution can come from particles that find their way to a dose point through these indirect paths. This is especially true for neutrons, which tend to backscatter more than photons. In such situations, the hand calculations can give the analyst a rough idea of the expected dose rates, but more accurate computer calculations are required to deal with these more complex configurations.

Shield design strategies

Both neutrons and photons have the property that the lower the particle energy, the more readily it is absorbed. Therefore, in selecting shield materials, the general principle is to select shield materials that effectively reduce particle energy and then absorb the particle once its energy is reduced.

For high-energy photon sources, the selection of materials is simplified by the fact that the most effective materials for reducing the photon energy are the same materials that most effectively absorb photons: dense, high-Z metals like iron and lead. These materials are effective in reducing photon energy because of their high electron density and are effective in absorbing photons because of large photoelectric effect interaction coefficients (This will be illustrated in “Sample Problem #1” section.).

For high-energy neutron sources, the selection of shielding materials is complicated by a number of physical considerations:

1. The most effective materials for slowing down neutrons above about 2 MeV are materials that have a high inelastic scattering probability. These tend to be high-Z metals (like is best for photons). However, since inelastic scattering is a threshold reaction

- (i.e., that once a neutron energy gets below a minimum value, the reaction is no longer possible), this material should be the first shield material encountered, but only thick enough to be the first collision the neutron has with the shield.
- Below the inelastic scattering threshold energy, the most effective atoms for slowing down the neutrons shifts to the other end of the periodic table—the low-Z materials (hydrogen being the most effective).
 - After neutron energy has been reduced, the most effective material are those special nuclides (like boron and cadmium) that have abnormally high neutron absorption probabilities for slower neutrons.
 - Beyond these considerations for the neutrons, the shield designer has to deal with the fact that neutron inelastic scattering and neutron absorption reactions both release photons. Therefore, effective photon shielding material has to be built into the neutron shielding as well.

The result of this is that neutron shielding tends to be combinations of high-Z, low-Z, and special neutron-absorbing materials, either in layers or mixed together. Special mixtures of concrete with steel aggregate (and sometimes with boron carbide added) have been found effective for neutron shielding (This will be illustrated in “[Sample Problem #2](#)” section.).

Computer codes

As with other engineering calculations, hand calculations of radiation transport (and resulting dose effects) have been systematically replaced with computer calculations as computers have gotten faster and more common. And, as with other engineering calculations, the approximate tables and function fits appropriate for use in design and analysis have both been transferred to more efficient computer implementations and improved upon by development of computer codes that utilize more rigorous transport calculations.

Automation of hand calculations

The most straightforward application of computational power to radiation shielding analyses is to simply port the hand calculation methods (described earlier) to the computer. Although this can be done through entering the appropriate data and equations into a spreadsheet, much of the tedium of such a process has been automated into available computer software (most of it sold commercially).

Software (e.g., MicroShield) is available that automates the uncollided and buildup equations described earlier for point sources shielded by lead, concrete, or water, and that commonly extends the capability with:

- Built-in source geometries beyond the simple point source described above—line sources, area sources, volumetric sources.
- Built-in shielding materials (usually with the user having the capability to describe other shielding materials) complete with data libraries for the included materials.
- Data libraries themselves, that not only include the attenuation, buildup, and dose rate conversion factors discussed previously, but also automate the determination of the source rate (yields, energies, and geometries).
- The capability to calculate the decay of the source materials, including daughter radionuclide production and the resulting effects on particle sources and decay heat production.
- Extensive capability to list and plot resulting dose rates for the convenience of inclusion in engineering reports, as well as advanced capabilities (useful to shield designers) to determine sensitivities of the dose to time, source dimension, shielding thickness or distance.

Solution of the radiation transport equation

A more rigorous and accurate approach to determining the dose rate maps is to solve the underlying equation that governs radiation transport, the Boltzmann Transport Equation ([Lewis and Miller, 1993](#)). Originally developed by Boltzmann in the late 1800s to apply to the diffusion of gasses through the atmosphere, this equation was adapted for use in nuclear reactor design, radiation shielding, and criticality safety applications in the 20th century,

The equation is:

$$\hat{\Omega} \cdot \vec{r} \phi(\vec{r}, \hat{\Omega}, E) + \int_0^{\infty} \int_{4\pi} \Sigma_s(\vec{r}, \hat{\Omega}' \rightarrow \hat{\Omega}, E' \rightarrow E) \phi(\vec{r}, \hat{\Omega}', E') d\Omega' dE' + \chi(E) \int_0^{\infty} \nu \Sigma_f(\vec{r}, E') \phi(\vec{r}, E') dE'$$

where $\vec{r}, \hat{\Omega}, E$ are the position, direction, and energy of the particle; $\phi(\vec{r}, \hat{\Omega}, E)$ is the angular flux at the specified point, direction and energy in particles/unit area/unit solid angle/unit energy; $\phi(\vec{r}, E)$ is the scalar flux at the specified point and energy (found by integrating the angular flux over all directions) in particles/unit area/unit energy; $S(\vec{r}, \hat{\Omega}, E)$ is the particle source rate in particles/unit volume/unit solid angle/unit energy; $\Sigma_s(\vec{r}, \hat{\Omega}' \rightarrow \hat{\Omega}, E' \rightarrow E)$ is the coefficient (referred to as a *cross section*) to be multiplied by the flux at point $\vec{r}$ to determine the scattering from $(\hat{\Omega}', E')$ to $(\hat{\Omega}, E)$ in units of probability/unit distance travelled/unit solid angle/unit energy; $\nu \Sigma_f(\vec{r}, E')$ is the cross section used to determine the number of neutrons produced from fission by a neutron of energy E' at point $\vec{r}$; and $\chi(E)$ is the energy distribution of fission-born neutrons per unit energy.

In the general case, there is no closed-form solution for the flux in the above equation, so the solution to the equation must be approximated. There are two principal approaches for implementing this approximation that have proven useful: deterministic and stochastic.

Deterministic calculations: The discrete ordinates method

In deterministic solutions to the transport equation, each of the phases (space, energy, and direction) are attacked using traditional numerical methods. Interestingly, experience has shown that each of them are better approached with different numerical approaches.

For each of the numerical treatments, the general goal is to replace functions of continuous variables (each of which can be evaluated at an infinite number of values of the variable) to a finite set of values that deliver an “accurate enough” approximation to the underlying functions.

Energy: the multigroup method

The energy dependence of the flux is approximated by dividing the energy range into a finite number of *energy groups* with interaction probabilities in each of the groups that can accurately reproduce the reactions rates for the energies within the group; this is referred to as the *multigroup method*. For most applications, this determination of multigroup parameters is performed with a combination of (1) pre-calculated values to account for the smooth, problem-independent energy dependence of the interaction probabilities (cross sections) and (2) special techniques to account for the problem-dependent contribution due to the presence of energy resonances—spikes or dips in interaction probabilities—that occur at specific energies characteristic to the isotopes in the materials.

The determination of appropriate multigroup parameters is seldom performed by the analyst, but the multigroup cross sections for common isotopes are collected into multigroup libraries for general use and available to users from sources like the Radiation Safety Information Computational Center (RSICC) at Oak Ridge National Laboratory in Oak Ridge, Tennessee.

It is the analyst’s responsibility to choose a multigroup library appropriate for the problem under consideration from the set of data libraries available from RSICC; in general, the important considerations for this choice are that the isotopes needed to describe the materials of the problem are included in the library and that the number of energy groups is sufficient to deliver the accuracy required by the analyst.

Direction: Quadrature integration

The directional dependence of both neutron and photon fluxes is approximated using a quadrature integration technique referred to as the *discrete ordinate method*. In this method, the flux is calculated at a finite number of particular (“discrete”) directions (“ordinates”) and these are combined using predetermined weights to estimate the direction-integrated (scalar) flux that is multiplied by the dose response functions to obtain doses or dose rates.

It is the analyst’s responsibility to choose a quadrature appropriate for the problem under consideration (usually from a set of quadratures built in to the computer code); in general, the higher the number of directions used, the greater the accuracy obtained (at the cost of increased computer time).

Space: Traditional finite difference

The spatial dependence of the neutron and photon fluxes is approximated using traditional finite difference techniques that are carefully formulated to conserve particles—that is, to assure that neutrons and photons are not non-physically created or destroyed due to the numerical treatment.

This conservation is usually accomplished by integrating the spatial flux over regularly-shaped spatial cells that contain a single material and then relating the cell averaged flux (for a particular direction and energy group) to the surface fluxes on each boundary of the cell in order to conserve particles.

These particle balance relationships for each cell result in an underdetermined numerical situation (that is, more unknowns than equations), so approximate auxiliary equations must be defined and incorporated into the equations. The most basic of these auxiliary equations is the diamond difference relations, in which the average cell flux is set equal to the average of incoming and outgoing boundary fluxes in each coordinate direction. This (or a similarly geometrically based) set of auxiliary equations generally restricts the problem geometry to regular orthogonal cells, limiting the ability of deterministic methods to model complex geometries.

Once the numerical approximations are made in the spatial, energy, and directional domains, the result is a large and sparse matrix equation. The solution of this linear algebra problem gives the average flux for each of the cells, energy groups, and directions; these can be used to approximate the true flux and from this produce an estimate of dose rates throughout the modeled geometry.

Advantages and disadvantages

The principal advantages of the deterministic discrete ordinates approach are:

- If the problem can be usefully simplified to one or two dimensions (e.g., a single wall, a set of concentric spheres, or a set of cylinders sharing the same axis), the resulting matrix relationship can generally be solved fairly quickly on a modern computer, not only allowing for quick solutions, but also for efficient parameter optimization.

- The resulting fluxes are found throughout the calculational geometry, making it well suited for the production of spatial dose maps.
- The accuracy versus discretization will generally increase by a factor of $1/N$ or greater, where N is the number of unknowns to be determined (i.e., product of spatial, energy, and directional subdivisions).
- The method can be effectively applied to adjoint flux. The equation that is the mathematical adjoint to the Boltzmann equation. Its solution measures the particle “importance” or effectiveness for contributing to the parameter of interest, such as dose. The adjoint flux is often precalculated and used to reduce the variance of Monte Carlo calculations (discussed below).

The disadvantages of the methods are:

- For 3D problems, the method is generally no faster than the more accurate Monte Carlo method.
- The analysis generally requires approximation of the problem geometry.
- The required discretization reduces the resolution of the answer in space, energy, and direction.
- Flux and dose profiles from two or three dimensional problems show the problem of ray effects, in which the limitation of particles to travel in only particular directions tends to result in profiles that show “waves,” with peaks in the calculated directions and troughs between them.
- The large number of unknowns requires large computer memory resources.
- There is no indication of the accuracy of the solution on the simplified model, so the user must estimate this by some other means (e.g., repeat calculations with different discretization).

Stochastic calculations: The Monte Carlo method

The stochastic (or *Monte Carlo*) method of calculating radiation transport involves a completely different approach to the solution of the Boltzmann transport equation. Although the Monte Carlo algorithm can be derived directly from the transport equations, the resulting random walk can be understood as a *simulation* of the physics of particle interactions.

Simulation of a radiation particle history

The Monte Carlo technique follows the lives (or *histories*) of multiple particles—simulating as closely as possible the actual events that would occur in the life of a particle, with the likelihood and outcome of those events following the natural distributions as closely as they are known. As the particle histories progress, the computer code collects information of interest to the analyst—reaction rates, reactions outcome, dose contributions, etc.—for each particle history and presenting an average of these contributions as an estimate of what the total physical system would produce. These information collections are referred to as *tallies*.

In contrast to the deterministic method presented previously, no numerical approximation is called for—except for what might be present in our best estimate of the natural distributions. Therefore, the results have the potential to be as accurate as possible with our current information. In fact, the principal source of inaccuracy in a Monte Carlo calculation generally comes from the fact that only a finite number of particle histories can be simulated in a finite amount of time. But other than this limitation, the Monte Carlo method is the so-called “gold standard” for solving reactor, radiation shielding, and criticality safety problems.

Of particular contribution to this preference for Monte Carlo solutions is the fact that complicated three-dimensional geometries can be modeled with much greater accuracy than with deterministic methods and the fairly complicated energy dependence of interaction cross sections (particularly for neutrons) can be directly incorporated into the calculation—without the need for the multi-group energy treatment.

In general, a particle history consists of using appropriate probability distributions to simulate the following events:

1. The original location of the particle.
2. The original energy of the particle.
3. The original direction that a particle is traveling.
4. The distance to the first (next) collision in the material.
5. The type of reaction that occurred in the material at the collision site.
6. (If the type of reaction results in the scatter of the original particle or emission of a different particle) The type, energy, and direction of the new particle emerging from the collision.

At this point, the decision tree returns to Step 4 for the next collision. This loop continues until either the type of reaction in Step 5 is a capture (without re-emission of any particle) or the distance found in Step 4 results in the particle escaping the geometry being analyzed.

Unfortunately, there are two serious limitations of the Monte Carlo method as applied to radiation shielding problems.

The first of these is a basic shortcoming of all Monte Carlo solutions: a precision (or error reduction) proportional to the square root of the number of histories run. So, for example, if an analyst wants the error reduced by a factor of 10, they must run 100 times as many histories as have previously been run. Since each successive digit of accuracy is so expensive, Monte Carlo radiation shielding calculations tend to run to a precision of only 1–5%.

This disadvantage is partially compensated by the fact that the statistical processing of the dose rates allows the method to tell the analyst the standard deviation of each of the requested outputs; in contrast to the “hidden” errors of the deterministic methods, the analyst knows the approximate uncertainty in the produced outputs.

The second of the shortcomings is that radiation shielding (in contrast to reactor or criticality safety analysis) tends to involve passage of the radiation through thick shielding, for which it is expected that only a small fraction of source particles will successfully penetrate. Since Monte Carlo solutions depend on simulations, this results in very low fraction of simulated particles contributing to dose rates at heavily shielding points in the geometry, with resulting large uncertainties in the results (or maybe no results at all).

Variance reduction techniques for stochastic calculations

The second disadvantage—the low efficiency of simulated particles penetrating shielding—can be mitigated through the use of techniques generally referred to as *variance reduction* techniques. These techniques can be divided into two rough categories: (1) techniques that increase efficiency by replacing the natural probability distributions with other distributions that encourage particles to contribute to tallies of interest to the analyst and (2) techniques that serve to better utilize computer time by amplifying the number of particles in “important” regions of the problem and culling the number of simulated particles in “unimportant” regions of the geometry. It is the analyst’s responsibility to specify the techniques for the computer code to use, making Monte Carlo radiation analysis a bit of an art form.

Variance reduction techniques assign each computational particle a numerical *weight*, which begins as 1.00 and represents the fraction of a physical particle that the computational particle represents.

The first category of variance reduction techniques emerge from the root of all Monte Carlo, the Law of Large Numbers, which relates the value of an integral (corresponding to a Monte Carlo tally) to the result of a stochastic process:

$$\bar{f} = \int \pi(x)f(x)dx = \lim_{N \rightarrow \infty} \frac{1}{N} \sum_{n=1}^N f(\hat{x}_n)$$

where: $\bar{f}$ is the weighted average of $f(x)$; $\pi(x)$ is the weight function used as the probability density function for choosing samples of x . It must obey:

$$\pi(x) \geq 0 \quad \int \pi(x)dx = 1$$

N is the number of samples; $\hat{x}_n$ is the n^{th} sample of x .

Comparing the integral to the stochastic equivalent, it can be seen that the two functions in the integral serve two different purposes in the stochastic process: (1) the distribution $\pi(x)$ is used to choose the sample values x used in the tally and (2) the function $f(x)$ is used in the tally itself.

The roles of these two pieces can be moved around a bit without changing the expected answer; in particular, if another probability distribution $\tilde{\pi}(x)$ is used instead of $\pi(x)$, the answer can remain unchanged if a corresponding change is made to the scoring function:

$$\bar{f} = \int \tilde{\pi}(x) \left(\frac{\pi(x)f(x)}{\tilde{\pi}(x)} \right) dx = \lim_{N \rightarrow \infty} \frac{1}{N} \sum_{n=1}^N \left[\frac{\pi(\hat{x}_n)}{\tilde{\pi}(\hat{x}_n)} \right] f(\hat{x}_n)$$

After such a modified distribution is used for a decision in the life of the particle, the particle weight is multiplied by the factor $\pi(\hat{x}_n)/\tilde{\pi}(\hat{x}_n)$.

The main variance reduction techniques in the category are:

1. Absorption weighting, which raises the probability of scattering to 100%, keeping particle histories from terminating by absorption.
2. Exponential transform, which increases the length of path segments in a desired direction (presumably toward a detector or desired dose point) and decreases the length of path segments away from the desired direction.
3. Source importance weighting, for which the user replaces the natural source spatial, energy, or direction distributions with preferential distributions (e.g., source positions closer to the detector, source initial directions toward the detector, source initial energies that prefer higher energies that are more penetrating, etc.).

The second category of variance reduction do not change any of the distributions that govern particle history, but have the user specify the relative “importance” of regions of the problem (with importance generally increasing toward desired dose points) and the computer code focusing its effort on the important regions.

Subsequently when a particle crosses between regions of differing importances, the weight might change in the following way:

- If the particle moves into a more important region, the computational particle is split into multiple computational particles in order to more thoroughly sample the region; the weight of the original particle is divided among the new particles. For example, if a particle crosses into a region with twice the importance of the region it is leaving, the computer code would divide its weight between two computational particles, each with half of the presplit particle weight.
- If the particle moves into a less important region, multiple particles are statistically combined into one by the computer code letting the crossing particle survive with probability p (commonly the ratio of the lesser to greater importance). If the particle survives, its weight is increased by a factor of $1/p$; otherwise the particle history is terminated.

These strategies work to better utilize computer resources without changing the expected result, resulting in lower uncertainties with the same calculational time. The bottom line is that a higher fraction of computational particles penetrate the shield than physical particles would, but the particles arrive at tally points with fractional weights; this greatly decreases the uncertainty of the calculated results.

The current state of the art of Monte Carlo analysis is to use approximate (and faster) deterministic methods to solve the adjoint form of the Boltzmann equation to determine the cell importances of the problem regions, and then to subsequently use these importances to increase the efficiency of the Monte Carlo simulations.

Advantages and disadvantages

The principal advantages of the stochastic Monte Carlo approach are:

- The capability to have near-exact geometry and complete energy-dependent cross sections for the materials in the problem. This largely eliminates errors introduced by geometric modeling approximations.
- The given estimate of the uncertainty of the reported values of interest to the analyst.

The disadvantages of the methods are:

- For almost all problems, the Monte Carlo method is much slower than lower-dimensional deterministic solutions; as a practical result, the analyst is usually limited to 1–5% accuracy in the dose rates beyond thick shielding.
- The errors in the tallies decreases as the inverse of the square of the number of histories run (and therefore as the inverse of the square of computer time required), which is very slow numerical convergence compared to deterministic methods.
- Without efficient variance reduction techniques applied, particle history simulations tend to be very inefficient in calculating doses beyond thick shielding.

Availability of computer codes

In the United States, the primary source of computer codes that have been developed at National laboratories (or submitted for free distribution by developers) is the Radiation Safety Information Computational Center (RSICC) at Oak Ridge National Laboratory in Oak Ridge, Tennessee.

In addition, other (usually proprietary) computer codes—some of which have been developed to interface with RSICC-distributed codes—are available for purchase or licensing from commercial entities.

A list of useful websites for finding and understanding these computer codes is presented below.

Research areas

At the current time the development of computer techniques and the application of those techniques to shielding problems of interest is an active area of research in nuclear physics and engineering. Current research papers and abstracts are available in the various publications of the American Nuclear Society (ANS) from their website at www.ans.org.

Sample Problem #1: 2 MeV photon source

To illustrate the use of both the hand calculation methods and a common computer analysis tool, a 2 MeV photon source sample problem, using the geometry shown in [Fig. 1](#), is considered. For this exercise, the problem was modeled in MCNP and the dose rates at the three indicated points (equally distant from the photon point source) are compared to the results of more approximate hand calculations.

A source strength of 1.345×10^{10} photons/sec was chosen so that the unshielded hand-calculated dose rate (using [Table 1](#) data) at each of the points would be 100 mrem/hr. For this problem (and “[Sample Problem #2](#)” section), we assume that the goal of the shielding is to reduce the dose rate at the entrance to the “maze” (near the lower right of [Fig. 1](#)) to below 1 mrem/hr, so the shielding needs to reduce the dose rates by about a factor of 100. This is, of course, about two tenth value thicknesses.

The principal problem parameters are:

- The walls are 10 cm thick lead walls (density 11.35 g/cm³)—corresponding to two tenth value thicknesses from [Table 1](#) data.
- Not shown in the figure are the floor and ceiling for the room, which have the same 10 cm thickness of lead; inner height is 300 cm and the point source is at the mid-elevation at the indicated (x,y) position.
- The MCNP calculation was run for 500 min (which resulted in a 1.7847×10^9 histories) to generate the dose rate map shown in [Fig. 2](#); the dose rates at the points P1, P2, and P3 were extracted from the dose map produced by MCNP.

Note that all three points that were selected have the same line-of-sight distance from the source (170 cm) and have the same direct-line shielding thickness (10 cm), so one would calculate the same dose rate with the hand calculation equation for each point. The problem was designed to show how the dose rate might be affected by three different scattering environments:

Fig. 1 Source, geometry, and materials of the sample problem.

- P1 at point (0,170,0)—with the source as the origin: There is a path by which the photons can reach the detector by bypassing the shield wall and there is a reflecting wall behind the point;
- P2 at point (170,0,0): There is no nearby bypass path, but there is a reflecting wall behind the point; and
- P3 at point (0, -170,0): There is neither a bypass path nor a reflecting wall behind the point.

The hand calculation parameters used (using data from [Tables 1 and 3](#)):

- $S_p = 3.7 \times 10^{10}$ photons/second
- $R(2 \text{ MeV}) = 7.45 \times 10^{-12} \text{ Sv-cm}^2$
- $r = 170 \text{ cm}$
- $t = 10 \text{ cm}$
- $\mu(2 \text{ MeV}) = 0.514 \text{ cm}^{-1}$
- $A_1(2 \text{ MeV}) = 11.66$
- $\alpha_1(2 \text{ MeV}) = -0.0206$
- $\alpha_2(2 \text{ MeV}) = 0.0149$

[Fig. 2](#) shows the resulting dose rate map; [Table 5](#) gives the results of both the hand calculation and the MCNP estimate of the dose at the three points, along with the percentage difference between the two methods. The hand calculation gives very good results for this problem.

Sample Problem #2: 14 MeV neutron source

The second sample problem is an analysis of a 14 MeV neutron source using the same basic “maze” geometry as in “[Sample Problem #1](#)” section. The source strength was again set to give us 100 mrem/hr unshielded dose rate at the three points; the

Fig. 2 Dose rate map from MCNP Calculation of the Sample Problem #1.

Table 5 Results of hand and MCNP calculations for Sample Problem #1.

Point	Hand calculation results			MCNP results	
	Uncollided dose rate (mrem/hr)	Buildup factor	Total dose rate (mrem/hr)	Total dose rate (mrem/hr)	MCNP/hand ratio
P1	0.581	3.089	1.795	2.162 (± 0.021)	1.205
P2				1.891 (± 0.019)	1.053
P3				1.895 (± 0.017)	1.056

resulting source strength is 1.739×10^8 neutron/second. The wall thickness was increased to 50 cm (chosen to be roughly two tenth value thicknesses of concrete for neutrons from Table 1); the same three dose points were used as in “Sample Problem #1” section.

Based on the more complicated considerations for neutron shielding discussed above, the shield material was designed considering a combination of regular concrete (contents shown in Table 6), iron, and boron carbide. A parametric study was performed to compare the expected shield dose reduction as a function of the volume fractions of each of these materials; a one-dimensional slab discrete ordinates calculation of 50 cm thickness with a 14 MeV perpendicular beam neutron source was used in this comparison, using the contents from (McConn et al., 2011) and the HILO2k shielding library from RSICC.

The results are shown in Fig. 3. From these results, it looks like a combination of iron and concrete is more effective than either of them alone; the results indicate that a dose reduction of about a factor of two can be obtained with iron contents properly chosen in the 40–70% range, which is (barely) credible as aggregate contents of a concrete mixture. Much less of a reduction is brought about by including the B_4C , but it might still be worth doing (depending on cost and the extra trouble that including it in the concrete “recipe” might cause for concrete cohesion and curing time).

Table 6 Isotopic contents of concrete mixture used (Material 89 from PNNL, 2011).

Isotope	Regular concrete (PNNL material #99) density = 2.35 g/cm ³		Concrete mixture (PNNL material #89) density = 4.50 g/cm ³	
	Mass fraction	Atom density (atoms/bn-cm)	Mass fraction	Atom density (atoms/bn-cm)
H	0.01	0.014039	0.008	0.021509
B	—	—	0.009	0.002256
O	0.532	0.047056	0.107	0.018124
Mg	0.029	0.001785	0.043	0.004794
Cl	0.034	0.001783	0.021	0.001605
Mn	0.337	0.016976	0.003	0.000148
Ca	0.044	0.001553	0.011	0.000744
Fe	0.014	0.000355	0.798	0.038724

For a simple comparison of a homogeneous shield versus a layered shield, a layered calculation was run on these same constituents: regular concrete, iron, and boron carbide. Since B₄C is a powder, two material layers were used: 20 cm of iron followed by 30 cm of 5 vol% borated concrete. (This preserves the total weight of the three material contents used in the “3 vol% B4C” curve at the 40 vol% iron point, which produced a dose fraction of 0.0225). The layered shield produces a dose fraction of 0.0167, a 33% dose reduction that might be worth the extra complexity of construction. We will assume, for this example, that the designers stay with the homogeneous shield design.

Rather than using the artificial mixture from this parametric study, a note of reality was added (to represent the real-life dialog that would have to happen between the shield designer and the suppliers of concrete) by restricting our choice of concrete mixture to those in [McConn et al., 2011](#) with a 50/50 or lower iron volume fraction in the mix. Looking at the available options from that document, the material 89 (“Concrete, M-1”) was chosen—as the one with volume fraction of steel closest to (without exceeding) 50%. The isotopic makeup of the material is given in [Table 6](#); since the atom densities of pure iron and boron in boron carbide are 0.084911 and 0.109858 atoms/barn-cm, respectively (Materials 158 and 40 from [McConn et al., 2011](#)), the iron volume fraction is ~45% and the boron carbide volume fraction is ~2%. (This is a very heavy concrete—almost twice the density of regular concrete.)

To gauge the expected effectiveness of this mixture, another one-dimensional discrete ordinate case was run for this material through a 50 cm slab, again with a 14 MeV perpendicular beam neutron source. The resulting fractional dose reduction as a function of depth in the shield is shown in [Fig. 4](#), along with an exponential least-squares fit (dotted line). Notice how thick the shield has to be before the asymptotic dose reduction starts to occur (due to scattered particles adding to the dose). Notice also the drop-off of the dose rate at the outer edge of the shield; this is because of the reduction in the number of backscattered particles. The estimated dose reduction factor through the shield is 0.0162, a bit better than the lowest point in [Fig. 3](#) (but not quite the factor of 100 we were looking for.)

Again, the MCNP calculation was run for 500 min like section “[Sample Problem #1](#)”, with about 8.5×10^7 histories, to generate the dose rate map shown in [Fig. 5](#). [Table 7](#) compares the results at the three points for both the MCNP calculation and the simplified

**Fig. 3** Results of 1D slab parametric study of concrete shielding contents.

Fig. 4 Dose reduction factor for the concrete mixture as a function of depth in the 50 cm shield.

Fig. 5 Dose rate map from MCNP Calculation of the Sample Problem #2.

Table 7 Results of 1D Slab and MCNP calculations for Sample Problem #2.

Point	1D Slab calculation results			MCNP results	
	Unshielded dose rate (mrem/hr)	Expected dose reduction from concrete mixture	Total dose rate (mrem/hr)	Total dose rate (mrem/hr)	MCNP/1D slab ratio
P1	100	0.0162	1.62	7.193 (± 0.097)	4.44
P2				2.113 (± 0.013)	1.30
P3				1.898 (± 0.012)	1.17

estimate of the dose from combining the uncollided dose and the 1D estimate of the shielding reduction. The simplified calculation gave only moderately high (but still useful) estimates of the dose rates at points P1 and P2, although it severely underestimates the dose rate at point P1.

Conclusion

The ability to analyze dose effects of radiation sources has been well developed over the 125 years since the discovery of radioactivity. A range of analysis methods is available to today's analyst that allow for accurate assessment of radiation transport applications.

Glossary

ALARA As Low As Reasonably Achievable, a guiding principle of radiation protection.

A.U. Astronomical Unit. The average distance between the centers of the sun and Earth, equal to 1.496×10^{11} m.

Dose Energy absorbed per unit mass.

Equivalent dose Dose multiplied by the LET of the radiation delivering the dose.

eV Electron volt, a unit of energy equal to the energy of an electron after passing through a 1 volt potential difference.

"keV" = 10^3 eV, "MeV" = 10^6 eV, "GeV" = 10^9 eV, "TeV" = 10^{12} eV.

GCR Galactic cosmic rays. The space radiation environment originating outside the solar system.

Gy Gray, a unit of dose = 1 J/kg.

HZE High energy ($E > 10$ MeV/nucleon) heavy ion ($Z > 2$) nuclei.

HZETRN High Z and Energy TRaNsport code.

LEO Low Earth orbit. Orbits generally within the innermost radiation belt and below.

LET Linear energy transfer, the amount of energy lost by an ion per unit length.

OLTARIS On-Line Tool for the Assessment of Radiation In Space.

SEP Solar energetic particles. Energetic protons, electrons and heavy ions emitted from the sun.

SAA South Atlantic Anomaly, the region of the inner trapped belt that dips to lower altitudes.

Sv Sievert, and unit of equivalent dose = 1 J/kg.

Introduction

On August 7, 1912, Victor Hess flew an electroscope on a balloon flight up to 5300 m and found the ionization rate at that elevation was three times that of the rate on the ground. Based on that and data from earlier flights, he concluded that the source of radiation was not from the sun, but of cosmic origin, making his measurement the first to detect and identify galactic cosmic radiation. One hundred years later to the day on August 7, 2012, the Radiation Assessment Detector aboard the Mars Science Laboratory Curiosity Rover made the first measurements of cosmic rays on the surface of another planet. Over that span of 100 years, detector technology advanced to develop instruments that simultaneously detect and identify protons, heavy ions, electrons, gamma rays and neutrons, yielding detailed information on the primary radiation environment in space.

Measurements at high altitude and in space have shown that the space radiation environment is much different than the natural and man-made radiation environment encountered on Earth. Particle energies can exceed tens of TeV per nucleon, and ion species span every natural isotope as well as electrons, positrons, and gamma rays. As such, different shielding strategies than the ones typically used on Earth are required to minimize the risk to astronauts and electronics from exposure. The health effects from exposure to radiation and the current National Aeronautics and Space Administration (NASA) standards for space activities are discussed in other chapters, and as such those topics won't be discussed here other than to note that radiobiology research is continuing in order to better understand the damage and effects from the high-energy components of galactic cosmic rays.

Mitigating the risk from exposure to the radiation environment for facilities in space requires an understanding of the particle species and energies from all sources, and then using that information to develop appropriate shielding strategies. This article first

discusses the components of the primary radiation field in the solar system and then outlines the shielding methodologies employed to mitigate the effects from that radiation. The article is divided into the following sections:

- Galactic cosmic rays (GCR)
- Solar energetic particles (SEP)
- Trapped belt radiation
- Shielding methodologies and materials
- Integrated shielding concepts

Galactic cosmic rays (GCR)

The ionizing particles that make up Galactic cosmic rays (GCR) present a risk to crews and electronics, especially for long-term missions. GCR originate outside of solar system and are made up of fully stripped atomic nuclei (98%) and electrons (2%), with the nucleonic component consisting of nuclei ranging from protons through uranium. The majority of the nucleonic component is protons (~87%), with helium nuclei the next most abundant (~12%) (NCRP, 2000). The rest of the remaining 1%–2% nucleonic flux is composed of heavier nuclei. In the solar system, the energies of GCR range from tens of MeV per nucleon up to 10^{14} MeV/nucleon, with the majority of the flux between 100 MeV per nucleon and 10 GeV/nucleon. The differential flux (expressed in units of number of ions per steradian per square meter per MeV per nucleon per second) of each GCR ion species generally peaks between 300 and 600 MeV/nucleon.

Although the fluence (time and energy-integrated differential flux) of high-energy heavy ions (HZE) with $Z > 2$ is only 1%–2% of the total nucleonic fluence of GCR, their contribution to free space (unshielded) dose is significant. Dose from charged particles is a function of mass stopping power of the ion, given by:

$$D = \left(\frac{1}{\rho} \frac{dE}{dx} \right) \phi$$

where D = dose, ϕ = fluence in units of cm^{-2} , and the term in the parentheses is the mass stopping power. Stopping power is proportional to Z^2 of the ion, and as such the contribution to the free space dose from each GCR nuclei is also proportional to Z^2 of the ion. **Table 1** shows the fraction each GCR ion contributes to the overall nucleonic fluence and dose in free space. Although HZE make up a small fraction of the total fluence, they make up almost 40% of the free space dose.

Upon entering the heliosphere at a distance of around 100 Astronomical Units (A.U.), GCR particles are affected by the sun's variable magnetic field and the resulting changing conditions of the solar wind. As the GCR particles propagate through the solar wind medium, three mechanisms are responsible for modulation of the GCR spectrum (NCRP, 2000). The solar wind (primarily low energy protons with a velocity around 400 km/s) acts as scattering centers, leading to diffusion (scattering). A second mechanism is convection due to the outward motion of the solar wind, and the third mechanism is adiabatic cooling of GCR particles. Thus, depending on the magnetic field strength, associated solar wind strength, and the particle's energy, the shape and magnitude of the primordial GCR spectrum is altered inside the heliosphere, with the effect greatest for lower energy particles. Because the strength of the sun's magnetic field and solar wind depends on the 11-year solar cycle, the GCR spectrum inside the heliosphere is also a function of the solar cycle. During solar minimum (minimum solar activity and magnetic field strength), the GCR spectrum is at a maximum magnitude. At solar maximum, the GCR spectrum is at a minimum. The GCR spectrum also shows a clear dependence on the 22-year Hale solar cycle of alternating polarity of the magnetic field (Ross and Chaplin, 2019).

Due to the resulting cyclical time dependence of the local GCR spectrum, GCR shielding must take account of the modulation of the spectrum during the period of time in the solar cycle under consideration. Models have been developed that generate time-dependent GCR spectra which can then be used in transport model calculations. These models take the time-dependence into account using any of several indicators related to solar activity, including sun spot number, neutron monitor rates, X-ray flux measurements, and GCR flux measurements in spacecraft. Two of the more commonly used GCR models are the Badhwar-O'Neill 2014 model (BON14) (O'Neill et al., 2015) and the Matthiä model (Matthiä, 2013). Both models generally agree within 10% of each other and have been extensively validated against past GCR measurements. **Fig. 1** below shows GCR spectra for protons, He, C, and Fe ions as calculated by the BON14 model under solar minimum conditions.

Table 1 The fractional contributions to the total unshielded fluence and dose from selected nuclei of GCR.

GCR ion	Fraction of fluence	Fraction of dose
Proton	0.897	0.432
He	0.094	0.180
C	0.00256	0.0443
O	0.00242	0.0746
Si	0.000366	0.0345
Fe	0.000252	0.0821
All HZE	0.009	0.388

Fig. 1 Calculated GCR spectra for protons (light blue), He (orange), C (gray), and Fe (dark blue) ions. The calculations are from the Badhwar-O'Neill 2014 model, run under solar minimum conditions.

Solar energetic particles (SEP)

There is a continuous flux of protons and other ions emitted from the sun that make up the solar wind. However, the energies of these ions are very low, generally below 1 keV, and pose little to no risk from radiation effects. Much more damaging are the energetic ions emitted during solar events such as coronal mass ejections and solar flares.

The frequency of energetic solar particle events is correlated with the solar cycle, with the probability of an event the greatest around solar maximum. Particles emitted from the sun follow the solar magnetic field lines, and as such the intensity of the particle flux depends on one's location in space and time. Electrons, protons, and heavier ions are ejected during these events. Among the ejected nucleons, protons make up the vast majority of the flux, with energies up to 1 GeV and above. Once an event occurs on the sun, the particle flux increases over several hours or days to a maximum intensity, then experiences a decrease that can last several days. Events can have more than one burst, as well. Fig. 2 shows the proton flux at 1 A.U. as a function of time during the Halloween 2003 event. Three primary ejections produced elevated levels of proton flux lasting 2 weeks, with a maximum proton flux four orders of magnitude above levels during no solar activity.

Fig. 2 The proton flux at 1 A.U. as a function of time during the October 2003 event. Data from Jiggins P, Chavy-Macdonald M-A, Santin G, Menicucci A, Evans H, and Hilgers A (2014) The magnitude and effects of extreme solar particle events. *Journal of Space Weather and Space Climate* 4. <https://doi.org/10.1051/swsc/2014017>.

Each SEP event produces a unique energy spectrum and intensity. The energy spectrum generally follows either a power law or exponential distribution that drops off with increasing energy. **Fig. 3** shows proton energy spectra at 1 A.U. integrated over the entire event from four historically significant events: February 1956, November 1960, August 1972, and October 1989 ([Mewaldt, 2006](#)).

In most cases, the majority of the proton SEP flux lies below 50–100 MeV, requiring modest amounts of shielding to stop such energies. For example, a 100-MeV proton stops in 3.7 cm of aluminum. However, if caught in an intense SEP event without shielding, such as excursions outside a spacecraft or habitat, severe biological consequences, including death, can occur. In addition, SEP can cause significant electronic effects in thinly shielded satellites, probes, and spacecraft. As such, the development of space weather prediction and early warning systems to provide opportunity to seek shelter or place electronics into safe mode are important components of protection from SEP.

A repository of measured particle spectra from SEP events since the late 1990s is kept at the California Institute of Technology through a website (details in the Relevant Websites section) and can be used to select particular SEP spectra for source terms in radiation transport codes. The OLTARIS code maintained by the NASA Langley Research Center ([Singleterry et al., 2010](#)) allows the user to select from a list of historical SEP events when calculating particle fluences and doses behind shielding in space.

Trapped belt radiation

Any planetary body with a strong enough magnetic field will capture lower energy GCR, solar wind and SEP ions, creating a flux of energetic ions located in specific locations along the geomagnetic field lines, called trapped belt radiation. Once trapped by the magnetic field, the particles will traverse back and forth between the poles along the magnetic field lines. At the poles, particles can enter and interact in a planet's atmosphere, which on Earth creates the Aurora Borealis/Australis. Compared with GCR, the flux of particles within these belts is much higher, but with lower average energies.

Trapped belt radiation—Earth

Earth has two primary radiation belts, commonly referred to as the Van Allen belts, and has a transient third outer belt that appears to be produced by coronal mass ejections and can exist up to several weeks. The inner two belts are permanent, although Earth's geomagnetic field lines are moved and distorted by the sun's magnetic activity, leading to temporal variations in the trapped radiation environment. The intensity of particle flux within the belts is a function of the latitude and radial distance to the field line. Computational tools have been developed that will calculate the energy-dependent proton and electron flux values for Earth's radiation belts. The Air Force Research Laboratory maintains one of the most commonly used codes by mission planners, the AE9/AP9/SPM model (see Relevant Website section for details and download) ([Ginet et al., 2013](#)).

Fig. 3 Proton energy spectra in units of number per cm^2 per MeV as a function of proton energy in MeV. The February 1956, November 1960, August 1972, and October 1989 events are shown. Data generated from OLTARIS.

Earth's inner belt has an altitude that ranges between 600 and 8000 miles (950–12,800 km). It is primarily made up of protons with energies up to 400–500 MeV and electrons with energies primarily in the 100s of keV. There are electron energies that go up to several MeV, but at a greatly reduced flux. Most manned low Earth orbit (LEO) missions are below the inner belt. However, due to an offset of the Earth's magnetic dipole center and rotational center, there is a dip in the inner belt that extends down to an altitude of 120 miles (190 km) over the Atlantic coast of South America called the South Atlantic Anomaly (SAA). LEO missions with moderate orbital inclination will pass through the SAA several times per day and will encounter elevated levels of radiation during those passes, leading to an increase of a factor of 100 or greater relative to the dose rate from GCR in LEO, depending on the altitude during the time of the crossing. For reference, at an altitude of 400 km, the contributions to the dose rate from GCR and trapped belt radiation are about equal to each other, with a total dose rate of about 140 $\mu\text{Gy/d}$ behind shielding comparable to the amount found in the Russian space station MIR (between 20 and 30 g/cm^2 , on average) (Badhwar, 1997).

Fig. 4 shows an AP9 calculation of the proton flux experienced by the International Space Station (orbital inclination of 51.6 degrees, altitude of 470 km). There is a total flux of 2.9×10^6 protons per cm^2 per day, with approximately 75% of the flux below 100 MeV, and 93% of the flux below 200 MeV.

The primary concern for radiation protection in the inner belt is the protons because of their high energies. 100 MeV protons will penetrate 10 g/cm^2 (3.7 cm) of aluminum, for example. Inner belt electron energies are low enough that 1 mm of aluminum will stop over 95% of the flux (flux with energies 500 keV and below). In addition to radiation effects to humans and electronics, the charging of spacecraft and components from the capture of trapped belt radiation can also be a concern for missions that spend an appreciable amount of time in the inner belt.

Earth's outer Van Allen belt approximately extends from 19,000 to 40,000 km and consists mostly of electrons with energies between 10s of keV to 10 MeV. Protons are also present in the outer belt, with energies between 0.1 and 5 MeV. The radiation field within the outer Van Allen belt is of concern for many of the satellites orbiting the planet. GPS satellites orbit the Earth at an altitude around 20,000 km, and satellites in a geosynchronous orbit are at an altitude of approximately 36,000 km, placing both of these orbits within the outer belt. Many satellites are placed in eccentric orbits that carry them through the outer belt for periods of time.

Trapped belt radiation—Outer planets

All four gas giants in the solar system—Jupiter, Saturn, Uranus and Neptune—have strong magnetic fields and corresponding intense trapped belt radiation environments. Jupiter's magnetic dipole moment is 20,000 times greater than Earth's, creating trapped belts that extend out to 2,100,000 to 3,500,000 km from the center of the planet (Bolton et al., 2004). In addition to the capture of SEP, GCR, and solar wind, eruptions from the moon Io are also a source of trapped ions in the belts. Jupiter's moons are within the belts, and as such they sweep through the belts, removing some of the trapped radiation. There are three magnetosphere regions around the planet. The inner magnetosphere (inside of 350,000 km) is the source of the intense, high-energy electron, proton and heavier-ion trapped radiation around the planet. Measurements made by the Pioneer and Galileo probes indicated high-energy (> 5 MeV) electron fluxes of 10^6 to 10^7 electrons/ cm^2/s , and high-energy (> 80 MeV) proton fluxes up to values greater than 10^5 protons/ cm^2/s (Bolton et al., 2004). Pioneer 10 received an external dose of at least 5000 Gy from electrons and 10,000 Gy from protons. Inside the 3-mm of aluminum shielding, Pioneer 10 received at least 4500 Gy (Miller et al., 1976).

Based on existing measurements and physical modeling of the Jovian magnetosphere, two codes are primarily used to predict the radiation environment around Jupiter. The European Space Agency maintains the Space ENVironment Information System "SPENVIS" (spenvis.oma.be) tool that can be used to calculate the radiation environment anywhere in the solar system. The Jet Propulsion Laboratory maintains the Galileo Interim Radiation Electron model "GIRE", which will calculate electron and proton flux values (Garrett et al., 2012).

Fig. 4 Trapped belt proton flux at a 51.6-degree inclination, 470 km altitude, during solar maximum. Data generated from AP9 calculations.

Shielding methodologies and materials

As described in the previous sections, the space radiation environment is complex, consisting of particles over a wide range of energies. Adding to its complexity, the environment fluctuates based on its time during the solar cycle and the occasional appearances of solar particle events. In free space, the radiation environment consists of GCR and SEP. Near a planet with a significant magnetosphere, trapped belt radiation must be considered along with GCR and SEP. **Table 2** shows the primary particle species, energies, and current models used to compute the particle flux spectra from those three sources.

No facility on Earth is able to produce the entire space radiation environment, and testing of shielding materials in space is expensive and only relevant to the particular location and time of the test. As a result, transport model calculations are the primary tool used for the design of shielding used for a particular mission scenario. Both deterministic and stochastic (Monte Carlo) codes are used for space radiation transport, each with their own strengths. Deterministic codes are faster and are the engineering tool used to narrow the scope of shielding options. Monte Carlo codes are considered to be more accurate, but require more time to execute than deterministic codes. As such, Monte Carlo codes are usually used in the final design process rather than for trade studies.

The deterministic code HZETRN (Wilson et al., 1991) is the code used by NASA Langley Research Center for shielding design studies. The shielding design computational tool OLTARIS (Singletary et al., 2010) incorporates HZETRN and is widely used within the community. A number of Monte Carlo codes, such as Geant4 (Agostinelli et al., 2003), PHITS (Sato et al., 2018), MCNP6.2 (Goorley et al., 2012), FLUKA (Battistoni et al., 2015), and MARS (Mokhov et al., 2004), have developed physics models that handle the transport of the wide range of particles and energies that make up the space radiation environment. As particles transport through materials, they can slow down and stop in the material, slow down and exit the material with less energy, or breakup and create secondary radiation through nuclear and electromagnetic interactions. Both deterministic and stochastic codes incorporate stopping power formalisms for charged particles and nuclear and electromagnetic interactions for all particles.

Relevant measurements of radiation transport are needed for comparison with transport code predictions. Accelerator facilities are able to produce beams of relevant ion species and energies that can test the shielding properties of materials with respect to particular parts of the space radiation environment, and many measurements of dose, dose equivalent, and particle flux behind shielded spacecraft and probes have been made in space, providing a data base of experimental measurements that can be used to guide shielding design in space. In particular, these data are used for comparisons with radiation transport model calculations of those experiments in order to validate the codes and determine the uncertainties associated with their predictions of transport of the entire space radiation environment.

When comparing the shielding effectiveness of various materials against each other, they are compared at the same values of areal density, where areal density is equal to the thickness of the material times its density. One reason for this is the following: a material like carbon (graphite) has a wide range of densities. A 1-cm thick sample of graphite with a density of 2 g/cm^3 will have a different amount of dose reduction versus a 1-cm thick sample of graphite with a density of 1.5 g/cm^3 , even though they are the same material. If the thickness of the 2 g/cm^3 is reduced to 0.75 cm, such that both graphite samples have an areal density of 1.5 g/cm^2 , then the incoming radiation passes by the same number of carbon atoms and will experience the same amount of dose reduction. Another reason for comparing materials at the same values of areal density is that different shielding materials with the same areal densities have the same mass, a critical parameter in mission planning.

Transport code predictions and measurements have confirmed that shielding materials which contain hydrogen provide better results in terms of dose reduction due to two factors. One factor is that hydrogen provides the best stopping power per unit mass because of its charge to mass ratio of 1, whereas other elements have charge to mass ratios at or near 0.5. The other factor is that the hydrogen nucleus presents the smallest target for incoming ions, reducing the amount of breakup of heavy ions into more penetrating, smaller secondary fragments when compared to interactions with other target nuclei. **Table 3** shows experimental data on the percent reduction in dose from 1 GeV/nucleon Fe particles passing through elemental and composite targets (Zeitlin et al., 2006). The reduction in dose is normalized by the areal density of the targets used in the experiments (percent dose reduction per g/cm^2). Materials that contain hydrogen provide the largest dose reduction. Although aluminum is commonly used for spacecraft and satellites, it does not provide the dose reduction for GCR-like Fe ions that the composite materials provide. Results from these experiments and accompanying transport model calculations have led to polyethylene being chosen as the standard GCR shielding material against which all other materials are compared.

Using the Linear Energy Transfer (LET) values for all primary and secondary particles that penetrate the shield, a quality factor Q is applied to the dose from each ion to determine the dose equivalent behind shielding. Calculations of dose equivalent behind several thicknesses of aluminum and polyethylene shielding in a GCR environment were performed using several transport codes (Slaba et al., 2017). The calculations simulated an enclosed environment in space, where primary and secondary particles that

Table 2 Overview of source terms in the space radiation environment relevant to radiation effects to humans and electronics.

Source	Particle ion species	Energies	Source codes, catalogs
GCR	e^- , e^+ , p, He, $Z > 2$	up to 10s TeV/nucleon	BON14, Matthiä
SEP	e^- , protons, He	Up to 1 GeV/nucleon	See Relevant Websites section for a location of a catalog of events

Table 3 Percent dose reduction in 1 GeV/nucleon Fe ion passing through elemental and composite targets, normalized to unit areal density.

Shielding material	Percent dose reduction (per g/cm ²)
Carbon	3.86
Aluminum	2.34
Copper	1.36
Lead	0.40
Polyethylene	5.07
Lucite	5.04
Boron epoxy	4.0
LiF	3.8
Marsbar	3.1

Data taken from Zeitlin C, Guetersloh SB, and Heilbronn LH (2006) Measurements of materials shielding properties with 1GeV/nuc ⁵⁶Fe. *Nuclear Instruments and Methods in Physics Research Section B* 252: 308–318.

penetrate a shielding wall can then go through the enclosed space and interact in the back wall. In those calculations, the dose equivalent from all primary and secondary ions, including secondary neutrons, was determined for shielding up to 100 g/cm² thick. Fig. 5 (Fig. 13 in Ref. (Slaba et al., 2017)) shows that for aluminum shielding thickness beyond 20–30 g/cm², the dose equivalent actually increases with increasing aluminum thickness. For polyethylene shielding beyond 20–30 g/cm², there is only a slight decrease in dose equivalent.

Although the dose equivalent initially drops quickly as shielding is added, the calculations show an optimal shielding thickness of around 20–30 g/cm². In the case of aluminum, there is a detriment to going beyond that thickness. For polyethylene, there is little incentive to produce a slight decrease in dose equivalent given the cost to the mission to add more shielding mass. The reason for the increase for aluminum and the flattening of the curve for polyethylene is the buildup of light ions in the enclosure produced by particles that penetrate the front wall and interact in the back wall of the enclosed space. Going far beyond 100 g/cm², the dose equivalent curve will drop to lower values for any shielding material, but the cost to the mission becomes prohibitive.

Another feature of the results shown in Fig. 5 is that there is a minimum dose equivalent rate that can't be improved with additional shielding, which in turn has implications for either the duration of a manned mission or the determination of exposure limits for that mission. On a 3-year mission to Mars in an aluminum spacecraft and shelter, the total dose equivalent received by an astronaut during the mission is predicted to be between 1.5 and 2.1 Sv, using the calculated rates in Fig. 5. NASA's guidance on radiation exposure in space, found in NASA-STD-3001 (link to publication may be found in the Relevant Websites section), states "planned career exposure to ionizing radiation shall not exceed 3% Risk of Exposure-Induced Death (REID) for cancer mortality at a 95% confidence level to limit the cumulative effective dose (in units of Sievert) received by an astronaut throughout his or her

Fig. 5 Calculated dose equivalents behind various thicknesses of aluminum (left plot) and polyethylene (right plot) in a GCR environment, using several Monte Carlo transport codes and three different versions of the deterministic transport code HZETR. Figure courtesy Slaba TC, Bahadori AA, Reddell BD, Singleterry RC, Cloudsley MS, and Blattnig SR (2017) Optimal shielding thickness for galactic cosmic ray environments. *Life Sciences and Space Research* 12: 1–15, Fig. 13, page 9.

Table 4 Ranges of protons in aluminum and polyethylene.

Proton energy (MeV)	Aluminum $\rho = 2.7 \text{ g/cm}^3$	Polyethylene $\rho = 0.92 \text{ g/cm}^3$
10	0.171 g/cm ² (0.063 cm)	0.113 g/cm ² (0.123 cm)
20	0.575 g/cm ² (0.213 cm)	0.395 g/cm ² (0.429 cm)
30	1.180 g/cm ² (0.437 cm)	0.824 g/cm ² (0.896 cm)
50	2.928 g/cm ² (1.08 cm)	2.081 g/cm ² (2.26 cm)
100	10.01 g/cm ² (3.71 cm)	7.242 g/cm ² (7.87 cm)
200	33.31 g/cm ² (12.3 cm)	24.43 g/cm ² (26.6 cm)
500	148.9 g/cm ² (55.1 cm)	110.5 g/cm ² (120 cm)

career". The REID for an individual depends on sex and age, but it should be noted that current risk models show an exposure above 1.5 Sv exceeds the 3% risk of REID for most adults. Ultimately, exposure limits for a mission will be set by the guidance outlined in section 4.2.10.4 of NASA-STD-3001, which states "Exploration Class Mission radiation exposure limits shall be defined by NASA based on NASA-requested recommendations from the National Academy of Sciences, the Institute of Medicine, and the National Council on Radiation Protection (NCRP)".

As shielding thickness increases, the differences between the models' predictions becomes more apparent. The percentages next to each data point in Fig. 5 are calculated by taking half the difference between the extremes and then dividing by the average of the extremes, excluding the $N = 1$ and $N = 2$ versions of HZETRN.

For SEP shielding, most of the proton flux lies below 50–100 MeV, requiring a modest amount of shielding. For shielding of protons in the inner Van Allen belt, proton energies are also primarily below 100 MeV. Table 4 shows the amount of aluminum and polyethylene shielding required to stop protons of energies present in SEP and trapped inner belt spectra.

Although particle flux in a SEP event can be large enough to produce serious acute radiation effects, a thicker-shielded area within a spacecraft or habitat will provide adequate protection while waiting for the flux to decrease. During the initial buildup of particle flux in a SEP event, real-time monitors can alert personnel to the potential to seek shelter and place electronics into safe mode. The rise in flux can happen quickly, presenting an issue for personnel far from shelter, such as a lunar excursion located hours away from a habitat. If the transportation vehicle does not have a shielded shelter, shelter-in-place may be required, such as taking up a position along a crater wall or inside a lava tube.

Integrated shielding concepts

Shielding materials with high hydrogen content provide the best reduction in dose and dose equivalent, but many such materials, such as polyethylene, are poor choices for structural components. Research continues into the development of new, light-weight materials containing hydrogen and other elements with low atomic number that can be used for spacecraft and habitat construction, but to date aluminum remains the most used structural material in space. Innovative design, however, can utilize non-structural materials within a spacecraft or habitat to augment the shielding provided by structural materials that have less effective shielding properties.

Placement of water and food supplies along the walls of a spacecraft or habitat will take advantage of the hydrogen and low-Z elemental constituents of those materials to provide additional dose reduction. For example, on the ISS the walls of the sleeping quarters have been augmented with polyethylene blocks to provide additional shielding in a space where astronauts spend a sizable fraction of their time. The use of the transport model design tools discussed in the previous section will help guide mission planners in determining the best use of these non-structural, low-Z materials in the overall design.

In-situ resource utilization can reduce the cost of launching materials to missions on the Moon or Mars by using local materials for habitat construction. On the Moon, a relatively low-mass inflatable habitat can be sent to the moon, and once in place, lunar regolith (soil and rock) can be put on the structure as the primary shielding material. On Mars, one method of in-situ resource utilization is to combine the carbon dioxide atmosphere and water in the regolith to make a polymer binder that can then be used with the Martian regolith to make a solid structural material and radiation shield (see "Marsbar" in Table 3).

In general, the best solution for radiation shielding in LEO, free space, or surface operations is to use low-Z materials, especially materials with hydrogen content. Through materials development and integrated shielding designs, the principles of ALARA are applied to reduce dose while keeping mission costs affordable. As radiobiologists continue to determine the effects from the HZE and other high-energy components of space radiation, the risks of long term exposure to the low-dose, low-dose rate GCR and other components of the space radiation field will become better known. Better knowledge of the risks will in turn help mission engineers improve the state of the art in space radiation shielding.

"All HZE" represents all nuclei with heavier than He ($Z > 2$).

"Marsbar" is a target made of 85% simulated Martian regolith (rock and soil) and 15% polyethylene.

Glossary

Activity The rate of decay or transformation of a radioactive element.

Apoptosis Cell death that is programmed into the genetics.

Atrophy The wasting of cells with some dysfunctional systems resulting in a gradual loss of homeostasis.

Bcr-Abl gene This gene codes for tyrosine kinase (a cell signal enzyme) that causes uncontrolled cell growth and is causes chronic myelogenous leukemia (CML).

Carcinoma A malignancy of the epithelial cells arising from the endoderm or ectoderm layers in the three embryonic layers.

Chromosome Two intertwined strands of complimentary DNA that contains many genes as well as sequences that are not known to code for anything.

c-Sis group A group of proteins that are responsible for glioblastomas, osteosarcomas, and melanomas.

Deoxyribonucleic acid The molecule comprised of two polynucleotide that are coiled around each other in a double helix that carry all genetic information in the ordering of the cross-linked base pairs.

DNA See deoxyribonucleic acid.

Epigenetics The alteration of gene expression resulting in phenotypic changes that is caused by the physiological environment that can be in response to environmental pressures.

Eukaryote Cells whose DNA is organized into chromosomes in a distinct nucleus that describes all organisms except eubacteria and archaeobacteria (see prokaryote).

Fluence The time integrated flux for particles in units of $[n/m^2]$.

Flux The flux, Φ , is the transfer of energy in terms of radiative energy or particles across a surface $\bar{A}$ given by $\Phi = \oint \bar{E} \cdot d\bar{A}$ which for electric flux has units $[N \cdot m^2/C]$.

Gene A portion of DNA on a chromosome whose sequence of base pairs is the code to synthesize a specific molecule, e.g. a protein or enzyme.

Glioblastoma The most common primary, i.e. arising in the brain itself, brain tumor that has a poor prognosis.

Homeostasis The condition where there is an equilibrium to maintain physiological processes for cells, tissues, or organisms.

Leukemia A cancer of the white blood cells with four common cell types: acute lymphocytic leukemia (ALL), acute myelocytic leukemia (AML), chronic lymphocytic leukemia (CLL), and chronic myelocytic leukemia (CML).

Melanoma A carcinoma of the melanocytes in the skin.

Myc gene A regulatory and proto-oncogene on chromosome 8 that is related to Burkitt's lymphoma and carcinoma of cervix, colon, breast, lung and stomach.

Necrosis Cell or tissue death.

*Retired.

Oncogene A gene that when under certain physiologic circumstances can cause the cell to become cancerous.

Osteosarcoma A primary, i.e. arising from the bone itself, bone cancer that is among the small number of cancers that originate in mesenchymal tissues.

Phenotype The set of observable characteristics of an organism from the interaction of the genetic makeup and the environment.

Philadelphia chromosome The specific activated oncogene due to translocations of chromosome 9 and 22 that results in the development of leukemia.

Prokaryote A single cell organism with an organized nucleus, nuclear membrane, or organelles that describes bacteria and cyanobacteria.

Proto-oncogene A gene that can undergo a mutation and transform into a oncogene that precipitates a cancerous transformation.

Ras protein The regulatory protein responsible for adenocarcinoma of the pancreas, colon, and thyroid as well as myeloid leukemia.

Sarcoma A malignancy of the embryonic middle layer called the mesenchymal layer that usually are less responsive to chemotherapy, radiotherapy, and immunotherapy than carcinomas.

Src-oncogenes The oncogenes are responsible for colorectal, breast, ovarian, lung, breast, and brain cancers.

Introduction

Radiation is the emission or transmission of energy through electromagnetic waves or particles that can interact with matter. Energy deposition in biologic tissue must be sufficient to break chemical bonds or to damage structures (cell membranes, internal cellular structures, chromosomes, etc.) to result in significant damage. For common chemical species found in biology, the majority of the chemical bond energies are of the order of $\sim 2\text{--}6$ electron volts (eV) which is the energy required for free radical formation. Photons are attenuated by Rayleigh and Compton scattering, photoelectric absorption, and electron-positron pair production so that penetration is measured by mass attenuation coefficients (see the National Institute of Standards and Technology [NIST] <https://www.nist.gov/pml/x-ray-mass-attenuation-coefficients>). Photons from radioactive elements are in the x-ray (124 eV to 124 keV) and gamma ray (a few keV to about 8 MeV) energies so that all are capable of bond breaks though lower energies will be near to the entry point of the radiation into the body. Radiation that does not break chemical bonds by direct damage or indirectly through other mechanisms such as free radicals will not have harmful effects. Radiation that breaks bonds is of biological significance and comprises the study of radiation biology. The bond breakage must occur in a biologically significant location that usually means in a cell nucleus. Breaking bonds and generating free radicals in interstitial spaces (outside of cells) cannot penetrate the cell membrane phospholipid bilayer to affect the nucleus. Thus, damage from all ionizing radiation is stochastic. Effects can be mild and local such a first degree sunburn to an unprotected patch of skin to more general and severe with third degree sunburn for prolonged sun exposure in a swim suit resulting in a large proportion of involved skin. In very severe cases such as exposure to the very high fluences of radiation due to an atomic bomb, thermonuclear bomb or a criticality accident, death can occur immediately or within days of the exposure. The book *"A Review of Criticality Accidents"* (McLaughlin et al., 2000) provides an excellent review of criticality accidents and can provide some understanding of the important factors for radiation exposure: distance, time, and shielding. Other important factors for radiation exposure include fluence, energy, and type of radiation.

It is estimated that humans are composed of 30–40 trillion cells. For a person to survive, they must maintain homeostasis, which is the ability of an organism to regulate physical and chemical processes to maintain an equilibrium that is specific for a type of cell. Cellular equilibrium means that chemicals must be within tolerances that are specific for the organism and cell type. Intravascular equilibrium are the normal ranges that patients receive when they have a routine chemistry panel. More specifically, human neural cells have a low intracellular sodium concentration but a high potassium that is exactly the opposite of the intravascular space (blood). So, for humans, intravascular (blood) homeostasis is maintaining the chemistry values on the typical panel but also refers to hormones, cell counts (white cells, red cells, and platelets), blood proteins, and other blood constituents that have normal ranges. So equilibrium conditions are dependent upon the organism and the cell type in the organism. When homeostasis is compromised, cells, and if extensive, the organism will cease to function normally. If the loss of homeostasis persists, cells (and the organism) will die when the excursions from normal are severe and persist long enough to create a cascade of systems that, in turn, become abnormal. Cell's and organisms, such as humans, have elaborate mechanisms to return the system to normal and maintain homeostasis. Thus, a small cut on an extremity will cause a localized loss of homeostasis, or drinking too much water can lower the level of sodium in the blood sufficiently to result in a generalized loss of homeostasis. If the cut is large and not addressed, the person can lose so much blood that there is a generalized loss of homeostasis which results in death after some time as the excursion from homeostasis becomes more pronounced. Likewise, a person with psychogenic water intoxication (a psychological condition in which the patient believes themselves to need to drink more water when they are actually overhydrated) will continue to drink too much water until the very low blood sodium will result in severe problems leading to death. So for radiation to cause serious immediate or near immediate (hours to days) problems, there must be a significant disruption in a person's homeostasis.

Sunburns are illustrative because they are common, caused by a familiar form of radiation, and a sunburn is a condition experienced by most people at one time or another. Sunburns can be mild with reddening of the skin or severe with third degree burns as well as be confined to a small area or generalized. Third degree sunburns covering a large portion of the body's surface area are life threatening conditions since the skin is so badly damaged that it cannot prevent large fluid losses and cannot protect from infections, i.e. cannot maintain homeostasis. The body loses homeostasis in widespread third degree burns. Sunburns also illustrate that in our environment, radiation is ubiquitous and that radiation in lower amounts is harmless. Low level light is used to read, do office and home activities, and enjoy the outdoors but a large dose of outdoor light can be harmful. Case in point, one can shine a flashlight at some point on the skin surface for a very long time with absolutely no ill effects because the low energy photons cannot damage molecular bonds or damage deoxyribonucleic acid (DNA). Whereas a relatively short time of sunshine on an area of skin can result in the radiation damage of a sunburn.

Sunburns also illustrate how the body responds to injuries affects what the extent and severity of the injury. When a sunburn occurs, part of the swelling is caused by direct cellular damage. The cellular damage releases cellular debris that triggers an immune (inflammatory) response with an accretion of white blood cells consisting of monocytes that mature into macrophages which are phagocyte (phagocytosis is the process of devouring and digest cells, bacteria, or viruses), lymphocytes, and neutrophils. These white cells and the cellular debris will cause capillaries to leak leading to localized edema (swelling) and nerves resulting in pain and tenderness. The body's response is to destroy bacteria and other pathogens and then to sweep the phagocytized pathogens out as quickly through the increased blood flow. Inflammatory responses result in normal, uninvolved cells to be damaged, so it is not ideal for all insults. The body reacts to all insults with inflammation designed to destroy pathogens even when the process does not include pathogens, i.e. a sunburn that is sterile though second- and third-degree burns can become infected. The body has a limited number of responses. Increased blood flow gets more nutrients and oxygen that helps the repair process but, in the case of third-degree burns, the increase blood flow exacerbates the fluid losses. So cellular damage leads to an inflammatory response that has both helpful and harmful effects.

Cells must also maintain homeostasis. If a cell loses its ability to maintain homeostasis due to damage from age or its local environment, it will die and release its cellular contents which attracts phagocytes to digest it. If enough cells are damaged or die in a local area, an inflammatory response will be triggered whereas a single cell may result in little inflammation. Direct damage by ionizing radiation on a cellular level is localized along the track because radiation (photons, ions, etc.) are small compared to the size of a cell and its organelles (specialized structures in a cell), but indirect effects, chemical bond breakage, from chemical species such as free radicals that have half-lives of only a few microseconds can cause damage, only approximately 30 Å from the initially generated free radicals from the track (Hutchinson, 1957). The effects are localized on the cellular level unless there is a large fluence of high energy radiation. In the case of sunburn, the damage occurs at the cellular level but since the ultraviolet photon fluence is very large, the affected area can be large too.

So, radiation in the form of electromagnetic waves (photons) and particles, both charged or uncharged, causes damage on the cellular level that can disrupt homeostasis. The damage can lead to cell death releasing cellular debris that can, if enough cells are damaged, trigger an inflammatory response. If this is widespread enough, then there can be a loss of homeostasis leading to illness and possibly death. Remember though that the body has many mechanisms to return to homeostasis.

Additionally, radiation can result in DNA damage breaking one or both strands of DNA. Cells have mechanisms to locate, identify defects, and repair damaged DNA. Single strand breaks are easily repaired but double strand breaks can be very difficult and may not be repairable (Frankenberg, 1984). It is estimated by Lodish et al. in *Molecular Biology of the Cell* (2004) that amazingly 10,000 to as many as 1 million molecular lesions per cell per day are successfully repaired from DNA damaged during normal metabolic function and environmental factors including radiation. This means that a single event is unlikely to result in a problem that leads to eventual cellular demise. Rather it requires many injuries in a short period of time or very significant damages such as a double strand DNA breaks. Should a defect in DNA not be detected and repaired properly, it may lead to a problem that will, in time, lead to cell death or a viable mutation. It can also lead to a defect that does not lead to cell death but some other dysfunction. Some of the mutations can lead to a cancer as is discussed below.

To have a clinically significant effect, energy transfer to cells by radiation must be sufficiently large to break chemical bonds and have a sufficient fluence that results in a dose that causes significant organelle damage, foils cellular repair mechanisms, or result in irreparable DNA damage. So that low fluence, low energy radiation has a lower probability of significant human morbidity and mortality. High energy radiation must typically have enough fluence to be statistically likely that the above damage occurs often enough to see clinically significant results. Clearly, being exposed to high doses (more than about 0.1 Gray, see glossary or below) of radiation in a very short time period such as the atomic bomb survivors in Hiroshima and Nagasaki and those exposed in criticality accidents where the dose was delivered on the order of a microsecond have significant morbidity (health issues). However, if the same dose is spread over many years, cells have ample time to repair DNA and other damage as compared to the enormous number of chromosomes damaged as well as identification and repair proteins that are damaged in a microsecond pulse of high energy radiation (see, for example, Rahu et al., 2013). High doses over short times (seconds) can overwhelm the ability of cells to identify and accurately repair the damage leading to severe injuries or death.

Radiation exposure data of workers in various fields who deal with radiation, who may be exposed to low doses (less than about 0.1 Sv) (see glossary or below) of radiation over relatively long periods of time, have been studied over the years to determine health effects. The Million Worker Study is a large cohort of workers in all aspects of radiation associated industries. The Million Worker Study has several sections submitted for publication and a few sections have been published. A brief discussion can be found in the conference proceedings listed (Sanders and Sanders, 2018). A summary table shows no statistically significant

risk for cancer though there are some possible relationships. The principal investigator on the Million Worker Study, J. D. Boice, Jr., notes (Boice, 2019) that

“the excess numbers of cancers associated with low-level radiation exposure, is so very small that it cannot be seen against the very high background occurrence of cancer in the population, i.e. a lifetime risk of incidence reaching up to about 38% (i.e. 1 in 3 persons will develop a cancer in their lifetime).”

It is important to understand that the 38% lifetime incidence of cancer is due to all causes such as from chemical irritants such as hepatocellular carcinoma due to carbon tetrachloride (a once common cleaning agent), environmental factors such as radon exposure, and genetic factors such as the presence of the BRCA 1 or 2 gene mutations (Breast CAncer susceptibility gene) that increases the risk of ovarian cancer by age 70 to 39% and 11% respectively while it increases the risk of breast cancer by age 80 to 72% and 69% respectively. These causes account for the lifetime risk of cancer. Consider lung cancer that has four common cell types: small cell carcinoma, large cell carcinoma, squamous cell carcinoma, and adenocarcinoma. Of those four cell types, only adenocarcinoma is not associated with cigarette smoking. Males smokers are 23 and females 13 times more likely than never smokers to develop lung cancer and account for 90% and 80% of the deaths from lung cancer (Finkelstein, 1996). So smoking is a clinically significant disease where a physician needs to know whether a patient has ever smoked and, if so, the pack years [average number of packs smoked per day times the number of years that the patient smoked] is an important historical fact since it is the dose of smoking. A heavy smoking history is 30 pack years. For those patients who have a history of heavy smoking, smoke now or have quit within the past 15 years, and are between 55 and 80 years old, yearly screening with low dose computed tomography scanning is recommended. Since so far there is no clear relationship between low dose radiation exposure and cancer (Boice, 2017), the same kind of history is not required (unless the patient is part of a study) and since there is no known associated lung cancer from low LET radiation, there can be no routine screening beyond the standards currently be employed as the standard of care.

Additionally, the standardized mortality ratios in the Mound Study of ^{210}Po workers (Boice et al., 2014) showed that the fewer workers had died than was expected as the “vital status was determined for 98.7% of the workers of which 3,681 had died compared with 4,073.9 expected (standardized mortality ratio [SMR] 0.90; 95% confidence interval [CI] 0.88–0.93)” and that “among the 4977 radiation workers, all cancers taken together (SMR 0.86; 95% CI 0.79–0.93), lung cancer (SMR 0.85; 95% CI 0.74–0.98), and other types of cancer were not significantly elevated” (Boice et al., 2014). These findings agree with previous, dated findings of no statistically significant relationship between cancer and low dose radiation exposure. This implies that there is not a clinically significant relationship between low dose (<0.1 Sv) radiation and cancer. In other words, there is no reason for a physician to inquire about radiation exposure history unless the exposure is to a high dose (0.1 Sv or higher) exposure because the relationship is insufficient. Asking questions in regard to exposure to heavy metals might be a pertinent question on certain circumstances because most heavy metals that are encountered in the nuclear industry are also chemical poisons whose harm is not from radiation but from chemistry.

Types of ionizing radiation

Important types of ionizing radiation in radiation biology include charged particles that possess enough energy to cause ionization such as negatively charged beta particles (electrons) and positively charged alpha particles (helium nuclei). Ionization is also caused by uncharged particles such as photons and neutrons that have enough energy to directly form ionized particles (such as free radicals) by photon interactions with electrons and by neutrons scattering with, primarily, protons. Nuclear transformations can result from gamma rays as in (γ, n) , (γ, p) , and $(\gamma, \text{fission})$ reactions or neutrons as in (n, α) and (n, p) reactions that will add to the total dose. [The notation (a,b) is a reaction with “a” entering the nucleus and “b” exiting the nucleus. The symbol before the parentheses is the initial atomic species, and the symbol after the parentheses is the final atomic species. For example, given the reaction $^{10}\text{B}(n, \alpha)^7\text{Li}$, ^{10}B is the target isotope and ^7Li is the product isotope. A neutron is absorbed by the ^{10}B and the excited nucleus decay by emitting an alpha particle, a photon, and ^7Li .]

Alpha particles are helium nuclei with two neutrons and two protons but stripped of its two electrons; thus, an alpha particle carries a charge of 2^+ (the two positively charged protons in the nucleus are no longer balanced by the two negatively charged electrons). In biological tissues, alpha particles can cause considerable damage on the cellular level because of the transfer of its kinetic energy to ionization of atoms and molecules over its range. For example, the approximately $10\ \mu\text{m}$ track of a 2 MeV alpha particle in tissue is essentially a straight line with energy deposited along the path but with a larger energy deposition at the end of the track in what is called the Bragg peak as shown in Fig. 1. The shape of the energy distribution resembles a teardrop with the majority of the energy deposited around the Bragg peak. Electrons are considerably lighter than alpha particles [the rest mass of an electron is $m_e = 9.109 \times 10^{-31}$ kg and the alpha $m_\alpha = 6.644 \times 10^{-27}$ kg so $m_\alpha/m_e = 7294$] so beta particles (electrons) scatter in random directions with other electrons associated with components of cells; thus, they have a path similar to a random walk. Energy is deposited all along the track of a heavy charged particle and for a short distance on either side of the track that is approximated by a teardrop.

Fig. 1 The alpha particle stopping power for the $^{10}\text{B}(n, \alpha \gamma) ^7\text{Li}$ reaction showing the energy deposition per unit length as a function of the remaining range and the Bragg peak near the end of the track.

For ionizing radiation traversing matter, the mean energy lost, dE_l , in a path length, dl , is called the linear energy transfer (LET) and is a linear approximation of the actual energy deposited below a cutoff energy and its geometry. The definition of the International Commission on Radiation Protection (ICRP) publication 103 (2007) for LET is used where dE is the mean energy lost by charged particle collisions with electrons while traversing a distance dl is:

$$\text{LET} = \frac{dE}{dl}$$

LET differs from stopping powers used in physics as stopping powers include all radiation (i.e. neutrons and photons) as well as charged particles and stopping powers approximate the actual energy loss per unit distance traveled through the energy absorbing medium as shown below rather than a linear approximate.

$$\text{SP}(E) = -\frac{dE}{dx}$$

Stopping powers are not linear and represent the energy lost traversing matter but are more complex to calculate. For example, the stopping power graph for a 1470 keV alpha particle from the $^{10}\text{B}(n, \alpha \gamma) ^7\text{Li}$ in air is shown in **Fig. 1** where the Bragg peak is seen. Linear energy transfer (LET) is a simplification that works well in most circumstances whereas others benefit from a full stopping power that has the Bragg peak. A full discussion of this can be found in textbooks on microdosimetry such as (Rossi and Zaider, 1996).

The topic of stopping powers is important at the level of cellular doses that constitutes the field of microdosimetry. Interest in the theory of energetic ions interacting with matter and slowing down dates back to Marie Curie's work in 1898–99 (Curie, 1900). Niels Bohr was the first to provide a theory of stopping powers (Bohr, 1913; Bohr, 1915) following the experiments of Hans Geiger and Ernest Marsden (1909) with Ernest Rutherford's theoretical explanation (Rutherford, 1911). Bohr did not take into account quantum effects that were first addressed by Hans Bethe (1930, 1932) that was later refined by Felix Bloch (1933a,b) and then by Ugo Fano (1963). The history of determination of stopping powers is well reviewed by James Ziegler (1999). The major contribution to the stopping power for ions is due to the electromagnetic interaction between the target electrons and the positively charged ion. The stopping power, SP, may be written as:

$$\text{SP} = \frac{dE}{dx} = \frac{\kappa Z_2}{\beta^2} Z_1^2 [L_0(\beta) + Z_1 L_1(\beta) + Z_2^2 L_2(\beta) \dots]$$

where

$$\kappa = 4\pi r_0^2 m_e c^2,$$

$$Z_1 = \text{ion charge},$$

$$Z_2 = \text{target atom charge},$$

$$\beta = \frac{v}{c},$$

$$r_0 \equiv \frac{e^2}{m_e c^2},$$

m_e = electron mass,

c = speed of light,

v = ion velocity,

and

$$L(\beta) = [L_0(\beta) + Z_1 L_1(\beta) + Z_2^2 L_2(\beta) \dots]$$

where L_0 is the stopping number that contains corrections to the stopping power. The primary stopping number, L_0 , contains the largest correction and [Fano \(1963\)](#) expressed it theoretically by:

$$L_0 = \frac{1}{2} \ln \left(\frac{2m_e c^2 \beta^2 \Delta E_{max}}{1 - \beta^2} \right) - \beta^2 - \frac{C}{Z_2} \ln(I) - \frac{\delta}{2}$$

where C/Z_2 is the shell correction for the target atom, $\langle I \rangle$, is the mean ionization energy of the target atom, and $\delta/2$ is the density correction. The largest possible energy loss in a single collision with a free electron is given by:

$$\Delta E_{max} = \left(\frac{2m_e c^2 \beta^2}{1 - \beta^2} \right) \left(1 + \frac{2m_e}{M_i (1 - \beta^2)^{1/2}} + \left(\frac{m_e}{M_i} \right)^2 \right)^{-1}$$

where M_i is the mass of the ion. The shell correction term takes into account the assumption that the ion velocity is much larger than the target electron velocity. The calculation requires careful accounting of the ion with the electrons in the various electron shells in the target. The mean ionization corrects for the quantum mechanical energy levels that target electrons have available for transfer. Finally, the density term corrects for polarization effects in the target.

The L_1 term is called the Barkas correction after the work by [Barkas et al. \(1956\)](#) and the L_2 term is the Bloch term. These terms deal primarily with two experimental observations. The first is that two ions of the same mass and velocity in the same target have different ranges where the only difference is for different sign of the ion charge. The other effect is the corrections required for the magnitude of the charge. For example, according to the basic Bethe-Bloch equation, an ion with charge +2 should have four times the stopping of a similar particle of charge +1 but experimentally the stopping exceeds a factor of four.

Alpha particles are produced in some nuclear decays such as radium ([Evans, 1974](#)) and thorium. Radium and thorium have been responsible for bone cancers (osteosarcoma and Ewing's sarcoma) in radium dial painters ([Rowland, 1978](#)) since both radioisotopes are deposited in bone in humans. Radon gas and its decay products inhaled by uranium miners is associated with the development of lung cancers ([Archer, 1976](#)). In general, isotopes of uranium that decay into isotopes of thorium that decay into isotopes of radium that decay into isotopes of radon gas which is the source of the radon found in uranium mines. In the radium mines of Schneeberg, Germany and Joachimstal, Czechoslovakia over half of the miners that died, had deaths attributed to lung cancer that presented at an early age. These uranium alpha particles do not penetrate skin so are not a hazard externally, but inhaled ([Harley, 1972](#)) or ingested alpha emitters do great damage to living tissues. It is always important to consider all risk factors that modify risks for cancer.

Beta particles are electrons emitted from the nucleus when a neutron transforms into a proton and electron. Commonly used beta emitters that have applications in university and commercial research are ${}^3\text{H}$ (called tritium), ${}^{14}\text{C}$, and ${}^{32}\text{P}$. Beta emitters of significant energy in the human body include the naturally occurring background radioisotopes ${}^{40}\text{K}$ and ${}^{14}\text{C}$. Potassium-40 (${}^{40}\text{K}$) isotopes ([Hardy, 1978](#)) are present among all naturally occurring potassium atoms at 0.012% (120 ppm) and release beta particles with enough energy to cause a dose of about 0.18 mGy (milliGray where a Gray is the measure of absorbed dose described below) in a 70 kg man in 1 year. This is the most energetic of the internal background isotopes. Carbon-14 (${}^{14}\text{C}$) is produced in the atmosphere as cosmic ray neutrons hit nitrogen nuclei and the nitrogen absorbs the neutron forming ${}^{14}\text{C}$. The energy ${}^{14}\text{C}$ releases in a 70 kg man in 1 year is about 0.01 mGy. Potassium-40 and carbon-14 combined are the greatest internal natural sources, which excludes radon, of dose in humans ([Oakley, 1972](#)). Other radioactive elements add far lesser amounts to the internal radiation of humans, and sensitive equipment can measure these small amounts of natural background radiation.

Gamma rays and X-rays are energetic photons (electromagnetic waves) that have the same properties as all other electromagnetic energy, have short wavelengths, and travel at the speed of light. Since gamma rays and X-rays are energetic photons, they penetrate biological tissue to a very deep level. For example, a 500 keV photon has a penetration depth of 10 cm in a four component tissue sample where the mass attenuation coefficient μ/ρ is 9.593E-02 (g/cm²) and the range is defined to be where the ratio of the intensity to the initial intensity is 0.37 (<https://physics.nist.gov/PhysRefData/XrayMassCoef/tab4.html>). Gamma rays come from transitions within the nucleus whereas X-rays come from transitions of the electrons around the nucleus, but the two are identical if they have the same energy (the identical wavelengths). An important radioisotope used in the treatment of thyroid cancers is radioactive ${}^{131}\text{I}$ that most often (89% abundance) emits 606 keV β^- particles and a 364 keV gamma ray (81% abundance). The ${}^{131}\text{I}$ is provided to the patient with the knowledge that iodine is taken up exclusively by the thyroid in doses that can kill the cancer cells.

However, healthy thyroid cells also up-take iodine. In the past, nuclear weapons testing released both $^{125}_{53}\text{I}$ and $^{131}_{53}\text{I}$ with both isotopes having up-take exclusively in the thyroid gland (Beierwaltes, 1963), salivary gland, and gastric mucosa adding to the total dose to the population with increases in cancers observed (Carter, 1977).

Understanding the reactions and processes on the cellular level and modeling those is area of study called microdosimetry (see Rossi and Zaider, 1996). Microdosimetry begins to explore the damage that occurs to a cell as a function of the actual energy deposition in the cell. A cell dies if it cannot maintain homeostasis that results from radiation caused damage. Cells have been described as little bags of chemicals, which implies a loose collection of randomly interacting molecules that have no relationship to the actual highly organized eukaryotic human cells (eukaryote cells have an organized nucleus where the DNA is organized into chromosomes and includes all organisms except eubacteria and archaeobacteria).

Cells have substructures that are called organelles. Eukaryote cells have a double phospholipid cell membrane that can sustain injuries and heals itself by the physics of the double phospholipid structure. Only damage that removes a large portion of the cell membrane that allows the contents to leak out will kill the cell with the immediate loss of homeostasis. The cell membrane encloses a number of organelles as shown in Table 1.

The DNA in a chromosome will uncoil a section of DNA that will be read by messenger ribonucleic acid (mRNA) which at a ribosome works with ribosomal RNA (rRNA) and with transfer RNA (tRNA) to construct proteins. Mitochondria are believed to be of bacterial origin, have their own DNA, and use the electron transport chain to supply energy for cell functions. Red blood cells have no mitochondria whereas hepatic (liver) cells may have 2000 mitochondria. Whenever a section of DNA is unwound for reading by messenger DNA, it provides a larger probability of interactions with radiation at the microscopic level due to geometric effects.

The largest likelihood for DNA damage from ionizing radiation occurs when a cell is dividing. At that time, the nucleus disappears, all chromosomes are unwound, and all the DNA is copied. The basic ideas are straightforward, but the mechanisms are complex to assure that the copy is exact. So tissues that are rapidly dividing are the most vulnerable such as cells in the bone marrow producing red blood cells, white blood cells, and platelets that are rapidly dividing. DNA damage in the bone marrow can result in a number of diseases but in particular leukemias. Fortunately, leukemias can be much more effectively treated now than in the past as stem cell transplants are being improved.

Microdosimetry looks at energy deposition damage at the cellular level. Usually, the calculations focus primarily on the total dose delivered to the cell and the dose delivered to the nucleus. Thus, microdosimetry is based on stochastic interactions between ionizing radiation and a cell and its nucleus. Energy deposition in the nucleus can lead to irreparable DNA damage that cause no problems (a section of DNA that does not code for anything), or lead to loss of homeostasis.

Protection from external radiation sources may be reduced by limiting time of exposure, increasing distance from the source (dose decreases by an inverse square law), and shielding. The ICRP report 103 (2007) makes the point that human exposure to radioactive substances should always be minimized no matter the estimated risk. Even though low level (less than 0.1 Sv) radiation has little likelihood of causing irreparable damage that results in a malignancy or death from loss of homeostasis, it is good policy to reduce the danger from chemical toxicity as well as radiation from heavy metals associated with reactors as fuel and waste products.

The Curie and the Becquerel

Marie Curie discovered radium and polonium (Nobel Prize in Physics 1903 and Nobel Prize in Chemistry 1911) and her daughter Irene (Nobel Prize in Chemistry 1935) discovered artificial radioactivity (where an element is made radioactive by irradiation) both are thought to have died of leukemia due to their exposure to radioactive elements in their experiments. To honor the Curie's family as multiple winner of the Nobel Prize, the Système International (SI) unit of activity was originally the Curie. Activity is the rate of decay or transformation of a radioactive element.

Since 1975 the SI unit for activity is the Becquerel named for Antoine Becquerel (Nobel Prize in Physics 1903) who discovered radioactivity from uranium compounds in 1896. Perhaps the first record of recognized biological radiation effects was when Becquerel left a radium container in his vest pocket and experienced skin redness (erythema) with ulceration requiring weeks to heal.

These units of activity are defined as:

Table 1 Eukaryotic cell organelles.

Organelle	Function
Centrosome	Forms microtubules that helps to transport molecules throughout the cell and aids in cell cycle progression
Golgi apparatus	Protein modification and transport
Lysozyme	Protein degradation
Mitochondria	Energy production via the electron transport chain
Nucleolus	Structure in the nucleus for ribosome biogenesis
Nucleus	Contains DNA along with repair and replication proteins
Peroxisome	Lipid degradation
Rough endoplasmic reticulum	Protein synthesis (has ribosomes)
Smooth endoplasmic reticulum	Lipid synthesis and detoxification

1 Bq = 1 disintegration per second.

1 Ci = 3.7×10^{10} disintegrations per second.

The rate of decay or activity is an exponential function and can easily be shown to be:

$$A = A_0 e^{-\lambda t}$$

where A is the activity at some time, t , with a decay constant of λ and an initial activity of A_0 . The half-life is determined by the time required for the activity to decrease to $\frac{1}{2}$ of the initial activity, A_0 , or

$$A = \frac{A_0}{2}$$

so that

$$e^{-\lambda t_{1/2}} = \frac{1}{2}$$

or

$$\lambda t_{1/2} = \ln(2)$$

which gives this relation for the half-life

$$t_{1/2} = \frac{\ln(2)}{\lambda} \cong \frac{0.693}{\lambda}$$

Protective quantities and absorbed dose

The ICRP report 103 defined dosimetric quantities in terms of protective quantities to relate energy deposited in organs in the body to radiation risk (detriment). The fundamental physical quantity is the absorbed dose, D , that is measured in units of Gray (Gy) where 1 Gy is 1 joule per kilogram (1 J/kg). The rad is the traditional unit of absorbed dose that is 62.4×10^6 MeV per gram and $1 \text{ Gy} \equiv 100 \text{ rads}$ where an electron volt (eV) is the kinetic energy that a single electron acquires when accelerated in a vacuum from rest through an electric potential difference of 1 V or 1.6022×10^{19} J. The absorbed dose is

$$D = \frac{d\bar{E}}{dm}$$

where $d\bar{E}$ is the mean energy deposited into the mass, dm , by ionizing radiation.

When ionizing radiation interacts with human tissue, damage that results is dependent on the energy of the particle and on the cell types in the tissue. There are some general findings that relate to detrimental effects: (1) ingested or inhaled alpha particle emitters do more damage than beta particle emitters; (2) tissue damage increases as the distance over which the ion travels is slowed to release ionization; (3) tissue in humans and animal model experiments with high cell division rates display increased damage (e.g. blood forming cells leading to leukemia) because, during cell division, the otherwise tightly folded DNA that makes it a small target since unwinding it increases the likelihood of interaction with a particle or electromagnetic wave that is also generating free radicals that diffuse a short distance before acting upon a molecule. As a particle interacts with matter, it slows down gradually with energy being deposited along the path of the particle as it travels through the tissue. LET approximates the energy transfer as a straight line with uniform energy loss all along its path.

In the context of radiobiology, detriment refers to the total health effect to a radiation exposed group and its descendants that has principal components from stochastic quantities including such things as cancer, inheritable defects, and premature demise. Radiation is assigned a tissue weighting factor, w_T , that is unique for each tissue, type of radiation, and energy of the radiation. The effective dose is the energy deposition from all radiation in a given tissue and is given by:

$$E_D = \sum_T w_T \sum_R w_R D_{T,R} = \sum_T w_T H_T$$

where w_T is the tissue weighting factor, $w_R D_{T,R}$ or H_T is the equivalent dose in a tissue or organ where weighting factors are dimensionless, and doses are in Gray $\left(\frac{\text{J}}{\text{kg}}\right)$. The system from ICRP provides a firm foundation to determine the effect of a type of radiation dose to a tissue and the likely detriment that is likely to be suffered. Please see Table 2 for some examples of radiation weighting factors and refer to ICRP publication 103 for more details on doses.

DNA strand breaks—Single and double, chromosome aberrations

Deoxyribonucleic acid (DNA) is the genetic carrier for life, consists of two strands of polynucleotides connected to one another by base pairs, and is wound into chromosomes in the nucleus of cells. This wound structure is a complex of control elements (histone proteins), enzymes for reproduction of the double helix before cell division, and ribonucleic acid structures to replicate proteins.

Table 2 Radiation weighting factors for different types of radiation.

Type of radiation	Radiation weighting factor, w_R
Photons	1
Electrons and muons	1
Protons and charged pions	2
Alpha particles, fission fragments, heavy ions	20
Neutrons	A continuous function of neutron energy

From ICRP publication 103, 2007.

Radiation damage to the nucleus may result in single or double strand breaks that require repair. If the damage is in an area of DNA (Muller, 1927; Lea, 1955) that is crucial for life the cell will die. If the damage activates genes that lead to pre-cancerous cellular changes then time and additional cellular insults may lead to the development of carcinomas, sarcomas, or leukemias (more about this later in the article).

The radiation interaction with water may result in reactive hydroxyl radicals that proceed to damage DNA by breaking chemical bonds. The detection of radiation exposure in the nucleus of lymphocytes (a white blood cell) is observed as chromosome breaks (Littlefield, 1991). Specific nuclear fluorescence dyes display chromosome damage in the form of inversions, deletions, and rings. Anaphase bridges may easily be observed during cell division. Researchers have found chromosome damage in subjects' years after exposure, for example Japanese atomic bomb survivors have observable chromosome aberrations many years after exposure (Doida, 1965).

Cell survival curves, DNA repair

In the laboratory established animal and human cell lines may be irradiated and seeded to petri plates to observe cells forming colonies. Cell survival curves account for the plating efficiency or number of colonies grown divided by the number of cells plated with no radiation, this is done first. After irradiation, the surviving fraction is the number of colonies grown divided by the cells plated times the plating efficiency expressed as a percentage. The shape of survival curves for cells is plotted with dose on a linear scale and surviving fraction on a logarithmic scale (Fig. 2). At low LET radiation the curve starts out straight on the log-linear plot; at higher dose the curve bends as a function of dose. If cells are irradiated with high LET radiation of neutrons the curve is almost a straight line from the origin (Byrne, 1997).

Cell survival data for human cells under radiation treatment for cancer tend to follow a linear-quadratic relationship as seen in:

$$S = e^{-\alpha*d - \beta*d^2}$$

in which S is the fraction of cells that are surviving a dose, d, with α and β as constants of the linear and quadratic components of cell killing.

Fig. 2 Illustrative cell survival curves showing the linear quadratic nature of cell demise in radiation with different values of α and β taken from the literature.

Modifiers to radiation effects, oxygen effect and radioprotectors

Oxygen enhances the effects of X-rays, called the oxygen enhancement effect. Oxygen must be present at the time of exposure because, when irradiated with ionizing radiations, it produces free radicals that will make the damage permanent. In the absence of oxygen, the damage produced by X-rays can be repaired. This is important in the treatment of solid tumors due to the area of hypoxia in the center of the tumor mass. In standard photon radiation therapy, the patient is given a dose daily or 24 h between doses. This allows re-oxygenation of the hypoxic cells in the solid tumor. This is repeated 5 days in a row with the weekend off for recovery for a total of 6 weeks.

Radioprotective compounds have been studied and work by scavenging free radicals produced by ionizing radiation. US astronauts on lunar trips carried amifostine (Grdina, 2002) sold under the trade name Ethiol. This chemical, $\text{NH}_2(\text{CH}_2)_3\text{NHCH}_2\text{CH}_2\text{SPO}_3\text{H}_2$, is a phosphorothioate that is not reactive until the enzyme alkaline phosphatase removes the phosphorylated end of the molecule to allow scavenging of the free radicals. It is radioprotective for ionizing radiation.

Cancer

A brief aside concerning cancers that are also termed malignancies. Normal cells are able to determine when there are enough cells in a given tissue and cease cell division. Cancer cells have no such inhibition and continue with cellular division unabated. Often, there are visually obvious abnormalities in the DNA of the cancerous cells though all cancers have some sort of DNA abnormality. The unabated cancer growth causes a multitude of problems that, untreated, usually result in the death of the patient. Human malignancies are divided primarily into two groups where the most common cancers that are called carcinomas arise from the epithelial germ cell layer in the developing embryo. The other group of cancers are less common and arise from the mesenchymal germ cell layer in the developing embryo. As a generalization, sarcomas are more difficult to treat and often have poor prognoses. Some carcinomas are curable, though some have a uniformly fatal prognosis despite aggressive efforts to treat the disease.

In order for a cancer to spread by direct extension (growing larger) or through distant metastases (a very small nidus of cells break off the many tumor and travel via the cardiovascular or lymphatic system), a cell's DNA must have been altered, the alteration must not be fatal to the cell, must not prevent cell division, and must remove the inhibition to unbridled growth. Fortunately, most damage to DNA results in a fatal alteration or prevents cell division. When all conditions are present, the malignancy will grow. It is now understood that the immune system likely rids the body of many early malignancies and potential cancers are prevented by cellular repair mechanisms. Carcinomas and sarcomas that are discovered by physicians are usually causing significant problems.

How does DNA become damaged? One source of DNA damage occurs during cell division when a strand can be misread by the DNA polymerase, but the proof reading and error checking keep such events from being common. Another source of damage is from chemicals that alter or bind to the DNA. Ionizing radiation can form a chemical species called free radicals (a chemical species an unpaired valence electron or an open electron shell) that can chemically break bonds in DNA or, less often, the ionizing radiation can directly damage it. The energy loss along the track is not linear but rather teardrop shaped around the Bragg peak where the majority of energy is deposited and therefore the most damage is done. Free radicals from ionizing radiation tracks passing near or through the nucleus can cause a break in a single strand of DNA and less often a double strand break. Single strand breaks can be repaired accurately by a cell whereas double strand breaks cannot usually be correctly repaired. For a cellular DNA to be damaged beyond repair, it must experience a double strand break or many single strand breaks (that increases the possibility of the strands not being accurately repaired), there must be a very large number of ionizing particles producing many free radicals or rarely, a direct strike by a heavy particle, i.e. alpha particle.

Another important concept is that there must be enough energy to cause a chemical alteration to the DNA. That is the process of irradiation must result in multiple single DNA breaks or a double strand break that is difficult for the cellular repair mechanisms to successfully detect and repair the damage. There can be other damages that can cause the cell to lose homeostasis but only DNA damage will result in a malignancy. So, a large amount of energy in a short period of time such as a criticality accident or an nuclear detonation can cause immediate or short term loss of homeostasis. Such exposures and long term exposures to ionizing radiation can result in malignancies that lead to excess morbidity and mortality.

Oncogenes and cancer, radiation carcinogenesis, leukemia, and solid tumors

When cells are damaged, they normally progress to a cellular death (apoptosis). Cellular normal genes that are involved in grow and cell division may be mutated to proto-oncogenes and expressed in highly active states. With additional cellular mutations the proto-oncogenes may convert to oncogenes that proliferate and with other mutated genes form primary cancer cells.

Research in cell growth and differentiation has allowed for the discovery of dozens of proto-oncogenes that are usually involved in cell signal events and cell division. The Myc gene (a regulatory proto-oncogene) of Burkitt's lymphoma is a chromosomal translocation that moves a section of chromosome close to the enhancer area. The Philadelphia chromosome is the specific oncogene activation due to translocations of chromosome 9 and 22 resulting in the development of leukemia. The Bcr-Abl gene codes for tyrosine kinase (a cell signal) causing uncontrolled cell growth forming chronic myelogenous leukemia (CML).

The Src-family of oncogenes are responsible for colorectal, breast, ovarian, lung, breast, and brain cancers. The c-Sis group are responsible for glioblastomas (most common primary brain malignancy), osteosarcomas, and melanomas. Ras protein is a regulatory agent that is responsible for adenocarcinoma of the pancreas, colon, and thyroid as well as myeloid leukemia.

The ability of radiation to mutate DNA and cause sub-lethal damage provides for the activation of proto-oncogenes. The disruption of cell cycle regulation and the activation of receptors of cell proliferation allow for uncontrolled cell growth. Tumors that arise from embryological lining layers of ectoderm (skin and nervous system) or endoderm (digestive track) are called carcinomas. Tumors that arise from mesoderm, the embryological middle layer (bone and muscle), are called sarcomas. The white blood cells give rise to leukemia and lymphomas.

The Life Span Study of Japanese atomic bomb survivors is the primary source for estimating carcinogenic risk (Roberts, 1987). Leukemias have been linked to radiation exposure and show a dose response which is well described by a linear-quadratic dose response (Richardson et al., 2009). Solid tumors incident data are better fitted to a linear dose response. When comparing atomic bomb survivors to Chernobyl emergency workers both data sets for leukemia display a much higher risk at a given dose than other cancers (rapidly dividing white blood cells mutate to form leukemia). In both studies, excess risk has been observed as early as 2 to 5 years post exposure. Solid tumors of breast, lung (Yamamoto, 1987), and thyroid also display an association with radiation exposure, however the risk estimates are not as strong as for leukemia. A more recent study by Rahu et al. of Chernobyl cleanup workers from the three Baltic countries of Estonia, Latvia, and Lithuania found different results:

"the study of cancer risk in a cohort of Chernobyl cleanup workers from three Baltic countries revealed an elevated proportion of thyroid cancers in relation to the general male population; however, this finding could be attributable, at least in part, to more intensive medical examination, including thyroid screening. No excess of leukaemia cases or radiation-related cancers as a group was found."

So even in the extreme circumstances of trying to control the fires at Chernobyl, there has not been a statistically significant increase in cancers except for thyroid cancer. The only human organ that uses or stores iodine is the thyroid so any inhaled or ingested radioactive iodine would all be deposited in the thyroid. The lack of an association with other cancers is a significant finding.

Radiation effects on the embryo and fetus

Radiation to the developing embryo and fetus can cause multiple malformations. The dose, time of irradiation during gestation, and dose rate all have effects. In 1929–30s, medical professionals reported a relationship in the use of x-rays and microcephaly (a very small head with abnormal neurological function) in utero (Goldstein, 1929). The Russell's at Oak Ridge National Lab (Russell, 1965, 1966) reported on the timing of radiation during pre-implantation (0–9 days), organogenesis (10 days to 6 weeks) and the fetal period (6 weeks to full term). The types of congenital malformations are the same as observed in the general populations, however the number of malformations is greatly increased. The mental retardation and growth retardations are the main effects of low dose irradiation. A dose of 0.1 Gy (10 rad) to an embryo during gestation is considered a point at which a therapeutic abortion should be considered.

Radiation dose risk with mammography, X-ray and computed tomography

Everyone is exposed to natural background radiation on a daily basis. This radiation comes from cosmic rays, the earth's soil and rocks and even the food we eat. Radon is the largest source of background radiation that is commonly encountered. Diagnostic radiology (Bross, 1979) is the largest source of radiation exposure for almost all human populations. Dental (McKlveen, 1980) and medical X-rays account for a very small risk they pose for providing valuable clinical information. The risks are referred to as stochastic effects of radiation if that dose leads to carcinogenesis (Boice, 1977) or hereditary changes. When high dose radiation is used for the treatment of cancers, cures may be achieved. However, deterministic effects of radiation are also observed. These deterministic effects include transient erythema (skin redness), dry desquamation (skin dryness with possible cracking), moist desquamation (skin breakdown) where the return of basal skin cells cures this condition, and temporary epilation (hair loss). Late effects include skin atrophy (abnormally functioning and dying skin cells) and necrosis (dead skin cells) that may occur months or years after high radiation doses. Most patients exposed to high radiation treatment protocols are older and suffer life threatening cancers. The possibility of radiation induced cancers 10–15 years later is a real stochastic possibility (Brenner, 2000). Informed older patients willingly take the radiation risk of future cancers to enjoy many years of life now.

Cancer risk is expressed in terms of effective dose, the equivalent dose to organs multiplied by a weighting factor. The dose risk from mammography is reduced by employing mammography units with anodes of molybdenum or rhodium and filters for X-rays from molybdenum. The mammography must display a difference in the density of breast tissue. The radiation scatters in breast tissue from Compton scattering which degrades the contrast. The scatter is reduced with compression of the breast between a parallel paddle and the film screen. This process causes discomfort, but compression reduces tissue thickness and allows lower radiation

dose to be used. The fact that a mammographic exam may cause cancer is of concern. In radiation biology, it is assumed that the probability of induction of cancer in tissue with ionizing radiation is linearly proportional to the average tissue dose. A complete breast screening produces a mean glandular dose of 0.2–0.4 cGy. The risk of a fatal cancer from a mammographic exam over a lifetime of 20 mammograms is about 1 in 10,000. A Canadian study states that “it is seen that if the reduction in mortality owing to screening were 24%, 87 lives would be saved by screening in the 40–49-year age range, and 7.6 lives would be lost due to radiation-induced breast cancer, resulting in a benefit-to-risk ratio in lives of 11.4:1 (87 divided by 7.6) for our risk model” (Yaffe and Mainprize, 2011).

The computed tomography (CT) dose in a single CT slice tends to be in the range of 1 to 4 cGy at the skin and fall off in the middle of the head or chest. The whole body CT may contribute 10 cGy to the patient. CT scans involve higher effective dose due to the larger volume of tissue exposed. In small children, dose is adjusted to minimize the total effective dose. Typical values of effective dose for various medical X-rays are as follows in mSv; Body CT 10.6, cardiac angiography 7, upper GI 3, lumbar spine 2, screening mammograph 0.4, chest X-ray 0.025, dental X-ray 0.008.

Linear no threshold and hormesis theories

It is important to know the risks for serious disease due to a particular absorbed dose of ionizing radiation. Does a minimal absorbed dose exist below which there is no risk of a lasting deleterious effect? This question generates considerable debate. The linear, no threshold (LNT) theory is that the dose response curve is linear and predicts that there is no safe dose of ionizing radiation. The hormesis theory posits that low doses of radiation exposure actually induce protective systems that prevents cancers. At this time, there does not seem to be a definitive technique that can answer the question. It is important to examine the two theories in view of biology and physiology.

First, there is no debate that large doses of ionizing radiation, especially when delivered over short time periods, result in deleterious health effects. These theories deal with low dose exposure to ionizing radiation, often over many years. As noted above, the study of one million radiation workers has not detected a statistically significant relationship between low dose, low LET, radiation and cancer. For the Mound Workers in Ohio, not only was there no statistically significant relationship to cancer, but the expected total cancers was less than was expected for a matched cohort as noted above where the standardized mortality ratio (SMR) was found to be 0.86 and for lung cancer only the SMR was 0.85. So this cohort had a lower total lung and total cancer incidence than would be expected.

The concept for LNT is that a low absorbed dose can cause damage that results in significant deleterious effects. The radiation directly or through other processes such as free radicals must break DNA chemical bonds in the cell nucleus which is a stochastic process. The damage must result in a survivable mutation instead of leading to the more common apoptosis (cell death). The DNA damage must not be recognized and repaired by the several cellular systems designed to repair DNA errors. Such a sequence of events cannot be directly observed. That any absorbed dose of ionizing radiation can cause a cancer is a key concept of the LNT theory.

Hormesis contends that low dose radiation over long periods of time is of little danger and may actually be protective. This is based in cellular physiology where some systems can be induced when there is increased activity. As an example, consider alcohol dehydrogenase that is the first enzyme to begin to metabolize alcohol in hepatocytes (liver cells). When a person ingests alcohol on a regular basis, the hepatocytes will produce more alcohol dehydrogenase so that they can process more alcohol per unit time than someone who rarely or never drinks. Some studies have shown that there are inducible systems that provide radioprotection in cellular DNA repair (Dinant et al., 2007; Chatterjee and Walker, 2017) though other studies have shown that non-irradiated near neighbor cells are damaged even though the cell is not traversed by ionizing radiation. For a thorough review of radiation induced biological effects, see the paper by Shemetun and Pilinska (2019).

During all the normal activities of a cell, there will be errors and damage to DNA and other important molecules. As noted by Lodish et al. (2004), a typical human cell will address 10^4 to 10^6 such errors and damages per cell per day. Cells are very well equipped to detect and correct errors or damage to DNA. Also, some tumors cause an immune response that results in the elimination of diseased (including some cancerous cells) by phagocytes (cells that envelop and digest other cells). So for a low dose radiation to result in a cancer, it must cause damage DNA in a manner that it evades the multiple systems to detect and repair the damage. The damage must not result in apoptosis (cell death) due to a lethal change as most DNA alterations do. Then the cancerous cell must elude the immune system. The likelihood of such an event would be logically small and the lack of correlation between low absorbed dose radiation and cancer would support that logic.

Finally, it is most informative to consider an event in Taipei, Taiwan where construction of 180 buildings including schools, apartments (1700 units), and other buildings were constructed between 1982 and 1984 with recycled steel that was accidentally contaminated with ^{60}Co [$t_{1/2} = 5.3$ years] (Chen et al., 2007). The authors state:

“Approximately 10,000 people occupied these buildings and received an average radiation dose of 0.4 Sv, unknowingly, during a 9–20 year period. They did not suffer a higher incidence of cancer mortality, as the LNT theory would predict. On the contrary, the incidence of cancer deaths in this population was greatly reduced—to about 3 per cent of the incidence of spontaneous cancer death in the general Taiwan public. In addition, the incidence of congenital malformations was also reduced—to about 7% per cent of the incidence in the general public. These observations appear to be compatible with the radiation hormesis model.”

At this juncture, neither LNT nor hormesis have clear evidence to support it as the correct viewpoint. The above arguments support hormesis more than LNT but both have some logical issues and inconclusive research. It would seem that the fear and concern generated by the LNT theory is not warranted and that hormesis should be more highly considered. While it is reasonable to always strive to minimize radiation doses, it also makes sense to try to minimize the unfounded fears that many, especially the public, has of radiation.

Summary

Ionizing radiation can deposit energy into biological tissues that can damage systems that maintain homeostasis and the genetic information (DNA) that codes for all the components of the cell with the exception of mitochondria that has its own DNA. Damaged DNA can lead to carcinomas and sarcomas that are most probable in rapidly dividing tissues such as the bone marrow. There are clear relationships to cancers for large doses of ionizing radiation delivered over a short period of time such as seen in bomb survivors and victims of criticality accidents. Such exposures, though dangerous, are fortunately rare. The other extreme where people are exposed to low doses of radiation over very long periods of time have not conclusively been associated with an increased risk of cancers. So, a null hypothesis of “annual doses of low LET radiation below some low dose has no adverse effects on human health” cannot be rejected based on currently available data. Studies to demonstrate that there is not a dose below which it is safe has not been proved. At the present time, any excess cancers from low dose radiation delivered over a long period of time should have been extracted from the data so these doses are not clinically relevant risks. This effect is likely due to the ability of cells to repair errors in replicating DNA and other cellular tasks. Cells have many opportunities to make an error but are able to correctly repair most errors. Low dose radiation delivered over a long period of time provides cells time to repair damage whereas when a large dose is delivered over a microsecond there can be so much damage that the cell cannot complete all repairs accurately. Even when a cell becomes cancerous, the immune system may recognize it as a malignancy and destroy it (see, for example, [Davis and Bjorkman, 1988](#)). It is important to realize that not all cancers elicit an immune response and some can adapt to prevent immune attacks ([Ribas, 2015](#)).

The ICRP recommends limiting the absorbed dose for anyone working with radiation to the minimal amount required to carry out the job. Though a dose response for cancer has not been conclusively shown for low dose radiation received over a long period of time, the recommendation should be heeded to minimize any risk that might be present.

However, it is important to keep the risks in perspective with the benefits from the entire nuclear industry. Nuclear power is a clean source of electricity that can be safely operated for many years with no contribution to greenhouse gases that are associated with global warming. Radiation has truly revolutionized medicine with fast, safe diagnostic techniques to diagnose and treat disease. There have likewise been great advances made in therapeutic modalities using radiation. Imaging techniques allow greater national security from examining shipments entering a nation to screen for potentially dangerous items. As is gleaned in this encyclopedia, there are multitudinous ways that the nuclear industry make our lives better with from power generation to radiological imaging to radiation oncology to radiocarbon dating to improving our national security. There are risks associated with radiation and radioactive materials, but the risks of low dose radiation have not been shown to be clinically significant. Clearly, the benefits of the industry far outweigh the risks even for the workers involved in working with radiation.

It is important to continue to minimize exposures to keep doses as low as reasonably achievable that means maximizing distance, minimizing exposure time, and using shielding. We all know that the sun can cause severe burns, and can cause nausea, vomiting, myalgias, and other symptoms of radiation poisoning including death but it does not cause fear. Instead, we behave rationally and protect ourselves by limiting the time that we are exposed and using shielding (clothing, shade, or inside) though we cannot increase our distance from the sun. It is critical that we approach the entire nuclear industry in the same manner so that the marvelous diagnostic modalities and treatment modalities in medicine as well as the power to deploy them from nuclear power will continue to serve us all well.

Introduction

Ionizing radiation has many beneficial applications, including uses in energy production, medicine, industry, security, agriculture and research (Waltar, 2021; Hor-Lacy, 2021). Electricity produced by nuclear reactors covers a large fraction of the energy needs of the world (e.g., 20% in the U.S). Medical procedures using radiation have saved countless lives through detection and treatment of medical conditions. Irradiation of foods or radiation sterilization of medical equipment is used to kill germs without affecting the substance that is being disinfected. Large societal benefits also come from the use of tritium in reflective signs, ^{241}Am in smoke detectors, or x-ray spectroscopy in determining the structure of substances, such as antibiotics.

Ionizing radiation has the potential of inducing health hazards if not properly used or contained. At moderate and low doses of radiation, health effects that occur from exposure to nuclear radiation are stochastic in nature. That is, the probability of occurrence, not the severity of disease, depends on radiation dose. Stochastic health effects may occur many years after exposure. Estimates of risk of stochastic health effects, defined as the probability of disease in a specified time interval, are crucial for understanding and controlling the health impact of radiation exposure.

Malignancies (solid and hematopoietic cancers) are the most important stochastic health effects of exposure to radiation. Emerging studies indicate that some non-malignant diseases, such as cardio-vascular diseases, may be regarded as stochastic, but data on possible associations with radiation are only now being collected. Also, there is no conclusive evidence of major hereditary effects in humans. Thus, this chapter focuses on available data and on methods for estimating the risk of cancer as a stochastic health effect.

Estimation of risks of stochastic health effects

Evaluations of health risks in a population exposed to radiation can be performed based on (1) radio-epidemiological studies, which follow up a population after exposure and observe the occurrence of any increases in late health effects, or (2) assessment methods to predict risk using on models derived from previous epidemiological studies.

Radio-epidemiology is a scientific discipline that uses direct observations to determine changes in rates of disease in human populations and their association with radiation exposure. *Risk assessments* rely on calculations using mathematical risk models. Both exposed individuals and decision makers are interested in the possible health outcomes of an exposure immediately following an exposure event. Epidemiological follow-up of a population takes many years, perhaps the entire lifetime of the exposed individuals, while assessments can be carried out rapidly to quantify expected risks. Assessments are also especially important when exposed populations are small, and epidemiological detection of an effect is hindered by statistical limitations.

Health effects in a population are quantified as incidence (or mortality) rates, defined as the total number of new onset disease events (or total number of deaths from a disease) during a given period of time, divided by the total number of persons. Common measures of risk are the *absolute risk*, representing the probability of occurrence of a health event in a population, and the *relative risk*, representing the incidence or mortality rates of disease in an exposed group relative to incidence or mortality rates of disease in a non-exposed group. An *excess absolute risk* (EAR) is the rate of disease in an exposed population minus the rate of disease in an unexposed population. An *excess relative risk* (ERR) is the rate of disease in an exposed population divided by the rate of disease in an unexposed population, minus 1.0. The EAR and ERR quantities are related mathematically through the rate of disease in an unexposed population, which represents the *baseline risk* (B). The name “excess” is used to indicate that EAR and ERR represent the portion of the total risk related to radiation exposure only. In an epidemiological study, risks are associated with the magnitude of exposure by means of a dose-response relationship that relates an excess risk to radiation dose and to other variables such as age or sex. In risk assessments, the total or excess risks in an exposed population of interest are estimated using dose responses obtained from epidemiology.

Radio-epidemiological studies

Epidemiological studies of incidence or mortality of cancer can be classified as *occupational*, *medical* or *environmental*, according to the type of exposed population. Table 1 summarizes epidemiological studies by type of exposed population. *Occupational* studies focus on individuals exposed in their workplace, and include nuclear workers, uranium and other miners, and radiologic technologists who work in the medical field. *Medical* studies focus on patients exposed to radiation during diagnostic or treatment procedures. *Environmental* studies include members of the public exposed to natural sources of radiation (including residential radon), releases from nuclear industrial facilities, fallout from nuclear weapons testing, and direct radiation from nuclear detonations, as in the case of the Japanese survivors of the atomic bombings in Hiroshima and Nagasaki, Japan. In addition, epidemiological studies

Table 1 Categories of epidemiological studies.

<i>Epidemiological studies by exposed population</i>		
<i>Occupational</i>	<i>Medical^a</i>	<i>Environmental</i>
Nuclear workers from Australia, Belgium, Canada, China, Finland, France, Germany, Hungary, Japan, Korea, Lithuania, Russia, Slovakia, Spain, Switzerland, UK, USA	General Imaging Diagnostic imaging In-Utero imaging Computed tomography (CT) imaging	Atomic bomb survivors Hiroshima, Nagasaki
Category of workers Radium dial painters Medical radiologists Uranium & other miners Uranium processing Plutonium processing Radiochemical plant Research reactors Nuclear power plant Chernobyl cleanup Flight crew	Benign disease Spondylitis (x-rays) Gynecological disorders Tinea Capitis Tonsils Thymus Skin Hemangioma Peptic ulcers Tuberculosis	Natural radiation Yangjiang, China Kerala, India Childhood Cancer, UK

		Residential Radon Austria, China, Czech Republic, Finland, France, Germany, Italy, Spain, Sweden, UK, USA

^aStudies are organized by medical purpose: general imaging, and diagnosis or treatment of benign or malignant disease based on external or internal (systemic) exposures.

may carry out analyses on combined (or pooled) data from multiple populations (e.g., multiple worker cohorts, multiple medical cohorts, combinations of worker or medical cohorts, including or excluding the cohort of Japanese atomic bomb survivors).

Radiation epidemiological studies are periodically evaluated by the United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR), International Commission on Radiological Protection (ICRP), U.S. National Cancer Institute (NCI), U.S. National Council on Radiation Protection and Measurements (NCRP), and U.S. National Academies of Sciences' Biological Effects of Ionizing Radiation (BEIR) committee. Evaluations focus on the methodological quality of each study and are carried out with respect to (1) methods for estimating radiation doses; (2) methods of selection of study participants; (3) methods for measuring outcome; (4) sources of bias specific to study design; (5) methods to account for factors other than radiation that could affect the disease; (6) statistical methods; (7) study reporting; and (8) conflict of interest of authors.

Based on reports from these organizations:

- Risks of stochastic effects increase with increasing radiation dose.
- Risks of stochastic effects remain elevated throughout the lifespan of exposed individuals.
- For most cancers, risks of stochastic effects decrease with increasing age at time of exposure.
- Cancers frequently associated with radiation in epidemiological studies and with well-established risk estimates include *all cancers as a group, all solid tumors as a group, leukemia, thyroid, female breast, lung, colon, bladder, stomach, esophagus, brain and nervous system, and ovary.*
- Cancers occasionally detected and which have risk estimates often with negative lower limits are *kidney, liver, salivary glands, skin, rectum, uterus, prostate, bone, connective tissue, Non-Hodgkin's lymphoma, chronic lymphocytic leukemia, skin melanoma, and cancers of the pancreas, testis, and cervix.*

Recent radio-epidemiological studies of cancer are discussed below, while risk assessment methods and examples are discussed in the second part of this chapter.

Environmental exposures

Japanese atomic bomb survivors

The most thoroughly studied cohort of individuals for estimation of health effects of ionizing radiation is the Life Span Study (LSS) cohort, which includes survivors of the atomic bombs detonated in Hiroshima and Nagasaki, Japan. The LSS cohort includes more than 100,000 persons (> 80,000 exposed) which have been followed-up longer than 50 years, during which time more than 17,000 cancer cases and 10,000 cancer deaths were observed. Analyses of data from this cohort indicate that most cancer types can be associated with radiation exposure, and provide estimates of risks that are dependent on radiation dose, sex, age at exposure, and attained age or time since exposure. The cohort average dose to colon was about 120 mGy, with 79% of survivors receiving doses less than 100 mGy.

Analyses of data for most individual solid cancers and for all solid cancers as a group are available for cancer incidence (follow-up from 1958 to 1998; Preston et al., 2007) and cancer mortality (follow-up from 1950 to 2003; Ozasa et al., 2012). For hematopoietic cancers (leukemia, multiple myeloma and lymphoma) current risk estimates are provided by analyses of data in the LSS cohort with a follow-up from 1950 to 2001 (Hsu et al., 2013). The most current analysis of cancer incidence for all solid tumors combined includes an additional 11 years (follow-up from 1958 to 2009; Grant et al., 2017), with analyses of individual cancer sites being carried out at present time but not yet completed.

The LSS cohort represents a large population of both sexes and all ages which experienced a single acute exposure. This cohort has good dosimetry, a long-follow-up, large numbers of cases and good information on other factors affecting disease (e.g., smoking). Its possible weaknesses are a healthy survivor effect, referring to study subjects having to survive post-World War II living conditions, and the effect of better medical care than the general population in Japan received by study subjects in later years.

Fig. 1 compares estimates of sex-averaged excess relative risks (ERR) of solid cancer incidence and mortality at 1 Gy from analyses of LSS cohort data with follow-up periods of 1958–1998, 1958–2003, and 1958–2009, with ERRs obtained from selected

Fig. 1 Estimates of Excess Relative Risk (ERR) at 1 Gy for all solid tumors combined (Uncertainty ranges represent 95% confidence intervals, unless noted otherwise. Listed numbers of persons, percent men, numbers of cases or deaths and average doses are for entire cohort. The number of years represents the total follow-up duration.)

cohorts of workers and members of the public (discussed below). The ERRs at 1 Gy are consistent among studies, with central values ranging from 0.3 to 0.8 for cancer incidence and 0.3 to 0.6 for cancer mortality. The uncertainty ranges in estimated ERR at 1 Gy from studies of workers and members of the public are significantly larger than uncertainties in estimates from the LSS cohort, because of lower numbers of people and observed cases, shorter follow-up or lower doses.

Natural background of radiation

Epidemiological studies investigating associations between cancer and natural background radiation are categorized as studies of exposures to radon in homes and mines, and studies of exposures to gamma radiation.

Radon—Average levels of radon are about 0.4 pCi L^{-1} outdoors and 1.3 pCi L^{-1} indoors, with certain areas having indoor levels higher than 4 pCi L^{-1} and reaching 20 pCi L^{-1} or more. Lung cancer has been convincingly linked to residential radon exposures in epidemiological studies with reliable dose reconstruction, especially from analyses of data pooled from more than 10 cohorts from various countries. The risk estimates from these pooled analyses of residential exposures are compatible with the high-dose studies of radon-exposed underground miners.

High level natural radiation areas—Average dose rates of gamma radiation from terrestrial sources of naturally occurring radionuclides are normally less than 1 mGy y^{-1} . Areas of much higher natural background radiation can be found in Brazil, Iran, India, and China, where external gamma doses can vary from several times up to a hundred times normal levels, often exceeding 10 mGy y^{-1} . Radiation-related risks of cancer among residents of such areas were studied in populations living in Yangjiang, China (average of 2.1 mGy y^{-1}), and Kerala, India (levels varying from 1 to 45 mGy y^{-1}). Studies of these two populations did not reveal an increase in cancer associated with external gamma radiation, with negative ERRs per Gy reported for all solid cancer mortality in Yangjiang and incidence in Kerala.

Other studies of exposure to background radiation—A study of natural background radiation and childhood cancer was carried out in the United Kingdom using estimates of radiation exposures based on mother's residence at the child's birth from national databases. This study found a significant dose-response for leukemia in relation to red bone marrow dose from gamma radiation (mean dose 4 mSv ; range $0\text{--}31 \text{ mSv}$). Their estimate was consistent with the dose-response relationship from the LSS. There was a weak but not statistically significant relationship between radon exposure and leukemia, and no association between gamma or radon dose with any other childhood cancers. The UK study is currently being expanded and dose estimates refined.

Releases from nuclear facilities

Populations living near nuclear power plants—Several studies have been carried out worldwide (e.g., U.S., Spain, France, South Korea, Belgium, Canada, Slovenia, Slovakia, Ukraine; [Jabon et al., 1991](#); [Kim et al., 2016](#); [Desbiolles et al., 2017](#)) to detect increases in incidence or mortality cancer rates in populations living within 20 or 30 km from nuclear power plants. These studies focused on rather current day populations residing near relatively modern facilities which operated under normal conditions. In general, these studies reported either not significant or inconsistent increases in cancer rates, suggesting that health effects are non-existent or too small to be detected.

Chernobyl accident—The most important source of information on risks in the general population after the Chernobyl accident in 1986 comes from epidemiological studies of thyroid cancer in children internally exposed to ^{131}I , primarily from consumption of contaminated milk. Numerous scientific papers have been published and follow-up studies are still ongoing for cohorts from contaminated areas in Ukraine, Belarus, and Russia. Findings indicate that children and adolescents have elevated rates of thyroid cancer that can be associated to their thyroid dose from radioactive iodine, with higher risks at younger ages at exposure and with a suggestion that deficiency in stable iodine may increase the risk. Evidence on thyroid cancer risks in adults are less clear, as are increases in incidence and mortality from non-thyroid cancers and non-cancer diseases. Most recent studies come from a cohort of Ukrainian children with ^{131}I exposure estimated from measurements and interviews, who received several rounds of medical screenings for thyroid cancer. The linear dose-response for thyroid cancer is consistent with the risk from external acute exposure in the LSS. Similar results were reported in children from Belarus. Assessment of the effect of uncertainty in dose estimates did not significantly alter these risk estimates.

Techa river—The Mayak Production Association industrial complex, in Russia, was dedicated to the production of plutonium for the Soviet nuclear weapons program. In the early years of operation, from 1949 to 1956, large amounts of radionuclides were released into the Techa River, creating significant exposures to a population of about 30,000 residents of 41 rural villages along 250 km of this river. These residents are members of two cohorts, one for cancer mortality ([Schonfeld et al., 2013](#)) and one for cancer incidence ([Davis et al., 2015](#)), both including males and females of all ages. Members of the cohorts were exposed externally to gamma radiation from river sediments and flood-plain soil, and internally through ingestion of water and food products contaminated primarily with ^{89}Sr , ^{90}Sr , and ^{137}Cs , but also with ^{144}Ce , ^{95}Zr , and ^{95}Nb . Estimated cumulative doses to the stomach varied from 0 to 960 mGy , with about 90% of individuals receiving less than 100 mGy . Analyses of both incidence and mortality of solid cancers as group indicated statistically significant linear trends. The ERR per unit dose, shown in [Fig. 1](#), are compatible with those from other studies. An update of dosimetry including quantification of uncertainties in doses is ongoing, and revised dose-response analyses are expected.

Occupational exposures

Numerous cohorts of workers exposed to radiation in the nuclear, medical, and aviation industries have been established and followed up in recent decades. A common finding of studies of these cohorts is that, when compared with the general public, a working population has less chronic disease, longer survival, and may have less cancer and cardiovascular disease, depending on the many competing causes of cancer experienced by that population. Overall, a healthier working population would have lower all-cause incidence or mortality rates than the general population, with disease occurrence shifted to later in life. This healthy worker effect is measured by standardized incidence or mortality ratios defined as ratios of observed to expected illness-related cases or deaths in an occupational cohort, where the number of expected cases or deaths is determined from national rates adjusted to reflect the age and sex composition the cohort of workers. Selected epidemiological studies of nuclear, medical, and other radiation workers are described below.

Nuclear workers

The International Nuclear Workers Study (INWORKS; Richardson et al., 2015, 2018) provides an analysis of pooled mortality data of occupationally-exposed nuclear workers in UK, U.S., and France. The dose-response analyses indicate statistically-significant associations of mortality from leukemia and from all solid cancers combined with increasing dose. The ERR per Gy for all solid cancers, as shown in Fig. 1, is comparable to estimates from LSS and other worker studies. The average cumulative dose to the colon was 21 mGy among workers with a positive recorded dose and the distribution of doses was skewed (90th percentile, 53 mGy; maximum, 1300 mGy). Statistically significant and consistent estimates of ERR per Gy were observed when the cohort was incrementally restricted to workers having doses less than 200, 150 or 100 mGy, which indicates that the dose response is approximately linear.

INWORKS is based on a large cohort, with long follow-up and good dosimetry for external doses. However, workers had unaccounted or missed neutron and internal emitter doses which could potentially affect reported risks. Estimates of ERR per unit dose represent risks in adult male workers exposed to low-LET radiation, and they cannot be directly used to assess risks in cases of childhood exposures and are less relevant for estimating risks in adult women. Site-specific cancer mortality analyses in INWORKS have been carried out, but, except for leukemia, they produce imprecise risk estimates at this time. More reliable site-specific analyses are expected as the follow-up is extended and the cohort ages.

Medical workers

Stochastic health effects in medical radiation workers, such as carcinomas of the skin or leukemia have been reported shortly after x-ray diagnostic techniques were first used. With the development of radiation dose measurements, film badge monitoring, and personal and general radiation protection equipment (lead aprons, machine and building shielding), medical occupational doses decreased significantly, leading to a decline in observed leukemia, skin cancer, and female breast cancer in medical radiation workers. Radiologists, radiological technicians, and other medical workers with historical and modern day exposures are currently part of several epidemiological studies.

US Radiologic technologists—Radiation doses have been recently reconstructed for a cohort of US radiologic technologists of about 110,000 (mostly female) workers. Epidemiological studies to date found a significant dose-response relationship for breast cancer incidence in workers who started work before 1950, and elevated risks for all cancer mortality and squamous cell carcinoma incidence. However, no dose-response relationship for basal cell skin cancer was found in these workers, although skin doses were greater than 1 Gy in some individuals. Detailed dose-response analyses for individual cancer sites are ongoing, but statistical power is generally limited for sites other than breast cancer, due to low mean doses and relatively small number of cases.

Chinese medical X-ray workers—A study of solid cancer incidence in Chinese medical X-ray workers included individuals (80% males) who were employed between 1950 and 1980 at major hospitals in 24 provinces of China (Sun et al., 2016). Another group of physicians, who did not use x-ray equipment, was established as a control. The mean reconstructed cumulative badge dose was 250 mGy. A dose response was observed with a statistically-significant ERR per Gy at an attained age of 50 (Fig. 1).

Other studies of occupational exposures

Chernobyl emergency workers—Emergency workers from the Russian Federation who responded after the 1986 Chernobyl accident have been followed up from 1992 to 2009, to assess risks of solid cancer incidence and mortality (Kashcheev et al., 2015). Many of the cancers were diagnosed as a result of mandatory annual health examinations that started in 2003. The majority of doses (85%) were measured using individual dosimeters, while the remaining doses were estimated by different methods. Cumulative absorbed doses from external exposure to gamma radiation ranged from 0.1 to 1240 mGy (mean 132 mGy), with 46% of individuals receiving doses less than 100 mGy. Statistically significant linear dose responses were observed for both incidence and mortality, with estimates of ERR that are more uncertain but comparable with other studies (Fig. 1).

UK workers—Gillies and Haylock (2014) provided an updated analysis of cancer mortality and incidence in nuclear workers formerly employed by British Nuclear Fuels in the United Kingdom. The cumulative external gamma doses were less than 600 mSv with a cohort mean of 53 mSv. Statistically significant ERRs per unit dose, shown in Fig. 1, were found for both incidence and mortality. Estimates of ERRs for smoking-related and for non-smoking-related cancers were similar to the ERRs for all solid cancers combined, but with slightly larger uncertainty ranges.

Mayak workers—Workers at the Mayak Production Association experienced external exposures to gamma radiation, internal exposures due mostly to inhalation of plutonium and other alpha emitters, or a combination of both external and internal exposures. Lung, liver and bone are particularly affected by internal exposures to plutonium and other alpha emitters, and they have been studied separately. Studies of incidence and mortality of solid cancers other than lung, liver and bone (“non-LLB cancers”) focused on associations with external exposure to low-LET radiation. Workers received gamma doses as high as several Gy, with averages of 510 mGy in the incidence cohort and 350 mGy in the mortality cohort. Linear dose responses, with no evidence of non-linearity, were observed for non-LBB cancers for both incidence and mortality. Lower estimates were obtained when attempting to adjust for internal exposures to plutonium. The Mayak workers dosimetry system is being updated and revised dose–response analyses are expected.

Other worker studies—Many other cohorts of occupationally-exposed workers are being followed up in epidemiological studies. Compared with the studies discussed above, these cohorts are smaller and were followed-up for shorter periods of time. The following list describes such cohorts, for which ERR per unit low-LET dose for all solid tumors or all cancers excluding leukemia were estimated: (1) mortality in German uranium millers, (2) incidence among nuclear power plant workers in Korea, (3) mortality among nuclear power plant workers in Japan, (4) mortality in Canadian uranium processing workers, and (5) mortality in U.S. Rocketdyne workers. In all these studies, the estimates of the ERR were not statistically significant. Because these studies are rather small (i.e. small number of people and of cases) and have short follow-ups, they have low power to detect radiogenic risk. Results from these cohorts are expected to be more informative as workers age.

To increase statistical power, smaller worker studies can be pooled to create larger cohorts. A new, large-scale pooled study is now being developed with the aim of evaluating risk of cancer mortality from protracted doses less than 100 mGy by combining various groups of US workers, including nuclear weapons workers, nuclear power plant workers, industrial radiographers, medical workers, and “atomic veterans” (i.e., military personnel who witnessed atomic test blasts). This Million Worker Study is led by the NCRP (NCRP, 2018a; Boice et al., 2018). Current efforts are focused on epidemiological methods for obtaining complete and accurate follow-up for each cohort (e.g., confirming who is alive, and determining the cause of death) and on reconstruction of doses and their uncertainties. Worker studies often showed a healthy worker effect indicated by cancer incidence or mortality rates in the exposed group that were lower than those in a comparable general population; thus, analyses within the exposed group are required to assess a risk per unit dose, and to determine if risk is different at low doses than at high doses.

Medical exposures

Links between medical x-rays and cancer increases in patients have been observed since the 1950s, starting with an observation of a small excess of pediatric leukemia in the offspring of mothers exposed during pregnancy. Other studies showed increased breast cancer risks in women with tuberculosis who were monitored using fluoroscopy, in women with scoliosis who were evaluated with repeated x-rays, and increased thyroid cancer risks in patients treated in childhood for various medical conditions. Medical radiation exposure to the US population has increased by about 600% since 1980, with similar trends in other developed countries, leading to potential risks of future cancers in exposed patients. A significant part of the increase in population doses is due to the increase in the number of computed tomography scans (CT). This prompted the initiation of several studies of risk of cancer from CT scans, focused on exposures in childhood.

UK CT scan study—A retrospective cohort study in the UK included approximately 180,000 patients who were first examined with CT scans between 1985 and 2002 as children and young adults (ages <22 y) and who were followed up to 2008. Positive associations with radiation dose were observed for leukemia and brain cancer. The major concern about this and other CT scan studies is the potential bias in observed dose responses when the cohort includes patients that received CT scans due to pre-existing medical conditions. In this study observed risks were reduced, but remained statistically significant when patients who had an indication of cancer at the time of the scans and patients with previous unreported cancers were eliminated.

Australian CT scan study—An Australian CT scan cohort includes approximately 680,000 children who had CT scans between 1985 and 2005 at ages <20 y, and approximately 10 million children who were not exposed. During a period of follow-up from 1985 to 2007, a total of 60,674 cancers were recorded, out of which 3150 cancers were observed in the exposed children. Overall cancer incidence up to 2007 was 24% greater in exposed than in unexposed people after accounting for age, sex, and year of birth. The observed dose response was expressed as an increase in incidence rate ratio for each additional CT scan. Current results are difficult to compare with other results because this study used the number of scans as a surrogate for organ dose. It is expected that radiation doses will be reconstructed, which should facilitate comparisons.

Other CT scan studies—The UK cohort discussed above and cohorts from Belgium, Denmark, France, Germany, Netherlands, Norway, Spain, and Sweden are expected to be combined and analyzed together in a pooled European CT study. This pooled study aims to include approximately one million children, with results due in the next few years. A Canadian cohort study that will include exposed adults is also in progress.

Other studies of medical exposures—Radiographic and other diagnostic x-ray procedures continue to be a common source of medical radiation exposure. Doses from such procedures are typically one-tenth of doses of CT scans for the equivalent body region, suggesting that cancer risks from these procedures may too low to be detected. Studies of cancers from these procedures face a number of challenges, including low statistical power and exposure misclassification, which may impede detection of a dose-response.

Radiological health risk assessment

A radiological risk assessment is the process of estimating risks of adverse health effects in a population exposed to ionizing radiation, using risk models available from epidemiological studies. Risk assessments can be carried out quickly following an exposure event to quantify expected risks, for the purpose of informing exposed individuals and decision makers. Risk assessments can be used regardless of the size of exposed population but they are particularly useful when populations are too small for epidemiological detection of an effect, with the extreme case being a single exposed individual.

One can distinguish between *retrospective assessments*, in which risks are estimated for past or existing exposure situations (e.g., Chernobyl accident, Fukushima accident¹) and *prospective assessments*, in which risks are estimated for future, potential exposure situations (e.g., astronauts traveling to and spending time on Mars).

How is a radiological health risk assessment carried out?

A risk assessment process starts with dose-response relationships obtained from completed epidemiological studies, which are used to calculate the excess risk of one or multiple selected health effects (e.g., leukemia, thyroid cancer, brain cancer, or all cancers combined) using estimated radiation doses in the exposed population of interest. A dose response is often called a “radiation risk model” and is described by mathematical equations that express risk (ERR or EAR) as a function of radiation dose, and, if possible, of sex-, age-, and time-related variables which allow for an estimation of risk customized to an exposure situation of interest. The risk assessment process also accounts for the radiation type (e.g., photons, alpha) and exposure rate (e.g., acute, chronic, fractionated) experienced by the exposed population.

Although human health risks from exposure to radiation have been extensively studied, there are still important sources of uncertainty which need to be considered and evaluated when estimating radiation risk (UNSCEAR, 2015). The sources of uncertainties can be divided into two categories: (1) uncertainties arising from analyses related to the derivation of a risk model in a selected epidemiological study, and (2) uncertainties associated with the transfer or application of the selected risk model to a different population, exposed to different radiation types and under different exposure conditions than those of the population followed-up in the epidemiological study.

Uncertainty in derivation of a risk model in an epidemiological study is introduced by (1) statistical analyses related to curve fitting of the number of health outcomes as a function of dose and other variables, (2) uncertainties in dose estimates for members of the epidemiological cohort, (3) uncertainties related to the number of health outcomes (i.e., cancer ascertainment, selection of study participants), (4) uncertainties related to other factors that affect the disease outcome (e.g., smoking, alcohol consumption, exposure to harmful chemicals, exposures to radiation from other employment or from medical procedures). These uncertainties can be minimized by evaluating and selecting a good quality epidemiological study, which includes a large cohort, large number of cases, long follow-up, good cancer ascertainment, good information about other factors affecting disease, and reliable dosimetry (UNSCEAR, 2016). Methods to address the effect of uncertainties in radiation doses assigned to members of the epidemiological cohort have been developed during recent years, with the purpose of reducing potential biases and properly quantify the magnitude of uncertainties in observed dose responses.

To date, estimates of mortality and incidence of cancer in the LSS cohort of atomic bomb survivors in Japan have been the most comprehensive source of information on radiation-induced effects. Cohorts of nuclear and other workers have been recently established and are being followed. They rely on advanced methods for cancer ascertainment, dose estimation and adjustments for other factors that influence disease. Pooling data from high quality cohorts of workers (e.g., INWORKS study) will likely create combined cohorts larger than LSS, which should allow for more reliable risk estimates at low doses. These cohorts have the potential of providing risk models representative for chronic exposures to radiation. Similarly, large cohorts of patients exposed to radiation for diagnostic or treatment purposes, which include individuals of all ages and both sexes, are being organized and followed-up in studies expected to provide information on risk from fractionated exposures.

A key issue in risk assessment exercises is how to apply risk estimates from a selected epidemiological study (e.g., LSS) to an exposed population of interest (e.g., U.S. workers). This transfer of risk between populations is primarily an issue for cancer sites that have substantially different baseline rates in the two populations, such as stomach cancer (higher in Japan than in the U.S.) or female breast cancer (lower in Japan than in the U.S.). Two approaches can be used to describe the transfer between populations: a multiplicative and an additive risk-transfer model. In a multiplicative model, the excess risk in the exposed population of interest is assumed to be proportional to the baseline risk of cancer in that population, with the ERR observed by epidemiology being applied directly as a multiplier to the baseline risk. In an additive model, the excess risk in the population of interest is assumed to be independent of the baseline risk in that population, and the EAR from epidemiology is considered representative and is applied directly. Both models are plausible on biological grounds (NIH, 2003), but they can lead to different estimates of risk when baseline risks in the two populations differ greatly (e.g., stomach, liver, female breast cancer for Japan and U.S.). The estimates of risk based on the multiplicative and on the additive risk transfer models define an uncertainty range for the true, but unknown risk, with the best estimate often considered to be an average between the two estimates. Risk transfer can be further customized by race as baseline rates of skin (and other) cancers are different in Whites, Blacks, Hispanics, Asians, or Native Americans. Exposures to

¹Information about these accidents and their impact on safety, licensing, and decommissioning are provided in the Chapter “safety, licensing, and decommissioning” of this Encyclopedia.

a second carcinogen, such as smoking or chemo-therapy agents, may affect the risk from exposure to radiation. The total risk from radiation and from another carcinogen is also calculated using multiplicative or additive interaction models between the two agents.

In order to estimate radiation risks, it is often necessary to extrapolate data obtained at high doses and high dose rates to low doses (< 100 mGy) or low dose rates (< 0.1 mGy min^{-1}), representative, for example, of exposures to populations living in contaminated areas after nuclear accidents, or of occupationally-exposed individuals. To estimate risks at low doses or dose rates, a risk calculated using a model from a population exposed at high doses and high dose rates (e.g., the LSS cohort) is often divided by a “dose and dose-rate reduction factor” (DDREF). In the 1980s, DDREF values ranging from 2 to 10 were estimated by NCRP and UNSCEAR based on data from animal experiments. In the 1990s, a DDREF equal to 2 was adopted by the ICRP and UNSCEAR, while in the 2000s, a value of 1.5 (95% CI: 0.8, 2.7) was recommended by the National Academy of Sciences’ BEIR VII report based on analyses of both animal and human data. Current analyses comparing risk estimates from many epidemiological studies showed DDREF values both lower and higher than 1.0. In its assessment of health effects after the Fukushima accident, the World Health Organization (WHO, 2013) did not use of a DDREF, thus advancing the idea that dose responses observed in LSS cohort require no further adjustments when applied to a population exposed at low dose rates.

Dose responses observed in most epidemiological studies are linear in dose, with statistical tests indicating the absence of a threshold dose below which the risk would be zero. Such dose responses have been observed mostly in studies with average cohort doses in excess of 100 mGy, with several studies indicating statistically significant responses below 100 mGy. These observations led to the assumption of a linear non-threshold (LNT) dependence on dose. However, there are a few epidemiological studies that indicate downward (concave) or upward (convex) dose responses, and various interpretations of data suggest existence of a threshold or hormetic dose responses (i.e., risks at low doses lower than in unexposed). The shape of the dose-response curve to be used in estimating risks at doses below about 100 mGy has been strongly debated for some time and some organizations advise against estimating health risks to people from exposures that are near or less than the natural background levels because of statistical uncertainties (HPS, 2020). However, an expert committee that recently reviewed epidemiological studies on low dose radiation concluded that data support the continued use of the LNT model in radiation protection (NCRP, 2018b). The use of an LNT model implies the possibility of either overestimating or underestimating the true risks at low doses. In risk assessments, this issue can be addressed by quantifying the uncertainty in estimated risks at low doses using an uncertain DDREF or using multiple alternative risk models. Decisions based on such assessments need to be made using the full uncertainty range of the resulting risk estimates.

Dose-responses from the major epidemiological studies represent exposures to low-LET radiation. Only a few epidemiological studies are available for cases of exposures to high LET radiation, and they are limited to exposures to alpha particles (e.g., from inhalation of plutonium or uranium or their decay products) and to a small number of cancer sites (e.g., lung, liver, bone). In practice, it is often necessary to evaluate the radiological impact of a large variety of high-LET particles including alpha particles, protons, neutrons of various energies, or heavy ions. Evidence from limited human, and somewhat more abundant animal studies indicates that high-LET radiation is more effective than low-LET radiation in inducing cancer. In the system of radiological protection, absorbed doses from high-LET radiation are multiplied by quality factors or radiation weighting factors,² which are intended to represent the enhanced biological effectiveness of each type of radiation relative to low-LET radiation. Similarly, estimation of risks in cases exposures to high-LET radiation is carried out using multiplicative factors, with the difference that such factors are customized for the risk assessment of interest (e.g., astronauts exposed to heavy ions in space) and account for differences in effectiveness of inducing leukemia and solid cancers. These factors are based mostly on animal data and include estimates of uncertainty in the possible effectiveness of each radiation type (Kocher et al., 2005; Cucinotta et al., 2013).

Estimated risks of radiation-induced cancer obtained from epidemiologic studies are used in establishing standards to control radiation exposures of workers and the public. However, cancer risk assessments generally *inform* the development of standards by advisory groups and national regulatory authorities, usually they are not *definitive* in regard to establishing limits on acceptable exposures. That is, as described below, standards to control radiation exposures usually are not related solely or directly to limits on acceptable cancer risks.

- With the exception of a standard in the U.S. to protect astronauts (described later), standards developed by advisory groups and national authorities do not specify limits on acceptable cancer risk associated with radiation exposure. Rather, most standards specify limits on quantities other than cancer risk, such as effective dose, organ dose, or concentrations of radionuclides in a source of exposure (e.g., drinking water).³
- The effective dose, which is widely used in specifying limits on acceptable exposures, is not always a valid indicator of cancer risks. In cases of highly non-uniform exposures of the whole body, which can result from intakes of some radionuclides and are common in exposures of medical patients, estimates of cancer risks at the same effective dose can differ by as much as an order of magnitude. Consequently, ICRP has cautioned that estimates of effective dose should not be used to estimate risks from actual

²Most recent radiation weighting factors are recommended by the ICRP Publication 103 (ICRP 2007) and have values equal to 1.0 for photons, electrons and muons, 2.0 for protons and charged pions, 20 for alpha particles, fission fragments and heavy ions, and 2 to 20 for neutrons of various energies.

³Standards for cleanup of radioactively contaminated sites established by the U.S. Environmental Protection Agency specify a *goal* of limiting the lifetime cancer risk to members of the public to no more than about 10^{-4} (one chance in 10,000 of a radiation-induced cancer). However, the risk goal is not a limit, and estimated risks well above the goal are allowed based on such considerations as technical feasibility and cost. Meeting the risk goal generally has not been feasible at radioactively contaminated sites.

or anticipated exposures. Limits on organ dose or concentrations of radionuclides in a source of exposure also may not be valid indicators of cancer risks.

Risk assessments are an important addition to radiation protection quantities, such as effective dose, especially in considering approaches to risk management and risk communication. For example, given the trauma and possible injuries or deaths associated with evacuation of affected populations and concerns about whether it would be safe for those populations to return to their homes, it can be important to make decisions about evacuation and return based on reasonably rigorous assessments of cancer risks.

Example radiological risk assessment exercises and estimation tools

Assessments of radiological risk are often used directly to assess existing or potential situations involving exposure to radiation. Collections of risk models and methods to estimate risk are available from various national and international organizations, including UNSCEAR, ICRP, NCRP or U.S. National Academy of Sciences (NAS). This section presents selected examples of risk assessment methods and risk assessment applications.

General risk assessment tools—In the U.S., the NAS develops up-to-date and comprehensive risk estimates for cancer and other health effects from exposure to ionizing radiation, through the activities of the Biological Effects of Ionizing Radiation (BEIR) committees of the National Research Council. The BEIR VII report (NRC, 2006) is the seventh in a series of publications concerning radiation health effects, and it is among the first reports of its kind to include detailed estimates for cancer incidence in addition to cancer mortality. In general, BEIR VII supports previously reported risk estimates for cancer and leukemia, but it is based on new and more extensive epidemiological data from studies of Japanese survivors of the atomic bombs, including updated radiation doses to the survivors based on the 2002 LSS dosimetry system (DS02).

On average, assuming a sex and age distribution similar to that of the U.S. population, the BEIR VII lifetime risk models predict that approximately one individual in 100 persons would be expected to develop cancer (solid cancers⁴ or leukemia) from a dose of low LET radiation of 100 mGy. By comparison, approximately 42 of the 100 individuals would be expected to develop solid cancers or leukemia from other causes (Fig. 2). Lower doses would produce proportionally lower risks. Thus, it is expected that approximately one individual in 1000 would develop cancer from an exposure to 10 mGy. The excess lifetime risk of cancer mortality is predicted to be about one half of the risk of cancer incidence.

The BEIR VII committee developed ERR and EAR risk models for 11 cancer types (stomach, colon, liver, lung, breast, prostate, uterus, ovary, bladder, thyroid and leukemia) plus a remainder grouping of cancers, based on the cancer cases in the LSS cohort. Using these models, lifetime risk and their uncertainties in either males or females can be estimated for one or multiple cancer types.

Fig. 2 Approximately 42 of 100 people will be diagnosed with cancer over their lifetime. Approximately one additional cancer in 100 people may result from a single exposure to 100 mGy of low-LET radiation (NRC, 2006).

⁴Excluding non-melanoma skin cancers

The largest lifetime site-specific risks in males are predicted for colon and lung cancers, followed by leukemia and bladder cancer. In females, the largest risks are estimated for breast and lung followed by colon, bladder and leukemia.

The U.S. National Cancer Institute (NCI) provided an extension of the analyses of radiogenic cancer incidence in the LSS cohort carried out by the BEIR VII committee, to include risk models for seven additional solid cancer sites (oral, esophagus, gallbladder, pancreas, rectum, kidney and brain), using the same epidemiological dataset and the same basic model formulation for the risk of solid cancer (Berrington de Gonzalez et al., 2012). The full set of risk models has been incorporated into an interactive web-based radiation risk assessment tool (RadRAT) which can be used to estimate the lifetime risk of radiation-related cancer with uncertainty intervals following a user-specified exposure history (<https://irep.nci.nih.gov/radtrat>). The calculator can be used to estimate lifetime cancer risk from single or multiple exposures with either non-uniform or uniform whole-body doses that are acute or chronic. It is most appropriate for low-LET radiation doses less than 1 Gy, and for individuals with life-expectancy and cancer rates similar to the general population in the U.S., although it can be adapted for other populations, by accounting for differences in baseline risks.

Compensation of radiation workers—An important application of radiological risk assessments is to provide the scientific basis for adjudication of claims for compensation for cancers that could have been caused by exposure to ionizing radiation. In 1985, the U.S. NIH developed specialized Radioepidemiological Tables to estimate a probability of cancer causation, defined as the likelihood that persons who have a radiation-related cancer and who received specific doses prior to the onset of such disease developed cancer as a result of these doses. The 1985 NIH Tables, which contained look-up tables of risk coefficients and appropriate equations, have been used by the Department of Veterans Affairs in a program to compensate military personnel who participated in the U.S. nuclear weapons testing program and later developed cancer.

The U.S. Energy Employees Occupational Illness Compensation Program Act (EEOICPA) of 2000 specified that the 1985 NIH Tables be updated and mandated compensation and medical benefits to eligible nuclear and energy workers (or certain survivors if the worker is deceased) for illnesses that could be related to exposure to radiation or other toxic substances while employed at U.S. DOE facilities. The process of updating the 1985 NIH Tables has led to the development an Interactive RadioEpidemiological Program (IREP), which is a Web-based computer code to estimate the probability that a given cancer in an individual was induced by past exposures to ionizing radiation. Accordingly, the National Institute for Occupational Safety and Health (NIOSH) adopted IREP for use in adjudicating claims under EEOICPA (U.S. DHHS, 2002). IREP can be accessed through NIOSH web-site (www.cdc.gov/niosh/ocas) or directly at www.niosh-irep.com/irep_niosh.

IREP calculates the probability of causation (PC) for a given cancer type as the risk from radiation divided by the total risk, defined as the risk from radiation plus the baseline risk in the absence of exposure. The probability of causation is expressed as a percentage between 0% and 100%. A probability of causation of 50% or greater means it is more likely than not that the cancer was induced by the past exposure to radiation. This occurs when estimated ERRs are greater or equal to 1.0 meaning that the total risk of cancer becomes double the baseline risk, due to radiation exposure. PCs are calculated based on the risk of cancer incidence estimated according to the age at time of exposure and the sex of the exposed person. IREP includes risk models for 33 cancer groupings and can accommodate estimation of PC for more than 90 individual cancer types, while accounting for up to 1000 prior distinct exposures to either electrons, photons, alpha particles, or neutrons of different energies. A defining characteristic of IREP is that it accounts for uncertainties in estimating cancer risks due to exposure to ionizing radiation and in evaluating causation of a given cancer in an individual. Part B of EEOICPA and its implementing regulations (U.S. DHHS, 2002) specify that eligible claims for compensation for cancer shall be granted when the upper 99% credibility limit of an uncertain PC is at least 50%.

Radiological risk assessment for astronauts—Another important application of radiological risk assessments is control of radiation exposures of astronauts, who are exposed to various sources of ionizing radiation throughout their career. Low-Earth-orbit missions aboard the International Space Station (ISS) and exploratory missions outside the Earth's magnetic field contribute to most of the expected increased risk of cancer in astronauts. Radiation exposures involve a mixture of low- and high-LET ions that are encountered in space. The most relevant fields are the galactic cosmic radiation, mostly energetic ions with atomic numbers 1 (H) to 28 (Ni), and secondary radiations (including neutrons) produced from nuclear interactions in shielding and the human body. In addition to cosmic sources of radiation present during space missions, occupational exposures of astronauts include low levels of atmospheric radiation during flight training on T-38 aircrafts and x-rays from medical imaging that are necessary for selection into the astronaut corps and flight certification.

NASA monitors the increased risk of cancer incidence and mortality over the lifetime of astronauts by recording their exposures and projecting the lifetime Risk of Exposure Induced Death (REID) and limiting it to less than 3% at the upper level of the 95% confidence interval. That career limit is called the Space Permissible Exposure Level. The projected increase in risk of cancer mortality limits the duration and number of missions that astronauts can fly in outer space. NASA performs both retrospective and prospective risk analyses, for past and future missions, respectively, using their specialized NASA Space Cancer Risk Models (NSCR-2012; Cucinotta et al., 2013), which were developed based on LSS data and adjusted to reflect the characteristics of the astronaut population and their exposures (non-smokers with expected survival longer than the average U.S. population who are exposed to space radiation).

Other radiological risk assessments—In early 1980, the U.S. Congress mandated scientific research to develop valid and credible assessments of exposure to ^{131}I that the American people received from radioactive fallout generated by world-wide atmospheric nuclear bomb tests, which resulted in estimates of radiation doses to the thyroid gland and estimates of lifetime risk of thyroid cancer produced by the U.S. NCI (cancer.gov/I-131; NCI, 1997; Simon et al., 2006). Radiation doses and risks of cancer from fallout of nuclear weapons tests have been estimated for individuals living near other test sites, for example the Semipalatinsk site in Kazakhstan or the Marshall Islands (Land et al., 2010).

Summary and conclusions

Ionizing radiation provides societal benefits, either through direct applications (e.g., power production, medical diagnostic or treatment) or through indirect uses (e.g., in agriculture, industry or security). Exposure to radiation is a well-studied carcinogenic risk factor in humans, compared with many other known or suspected carcinogens. Accurate estimates and proper interpretation and communication of radiological risks are important for operating a radiological protection system, and are necessary to maximize benefits from use of radiation by reducing potential adverse health effects. Estimation of radiation risks are carried out by direct observation of exposed populations in epidemiological studies or by risk assessments based on risk models derived from existing epidemiology. Such assessments are used to evaluate existing or future potential radiological exposure situations.

Numerous epidemiological studies of environmental, occupational, and medical exposures to radiation have been carried out to date. The life span study (LSS) of the survivors of atomic bomb detonations in Japan is considered the most reliable source of information on carcinogenic risks from exposure to radiation. Newer cohorts of radiation workers and of patients with radiation exposures from medical procedures are being developed, which are expected to provide information on radiological risks from chronic and fractionated exposures to radiation, with cumulated doses generally lower to those experienced by the members of the LSS cohort.

Risk assessments are powerful tools that can help in understanding the effects of radiation exposures. Proper communication of risks to interested parties is essential to avoid misinterpretations or exacerbations of preconceived and often incorrect views on effects of radiation. A common method for risk communication is a comparison of adverse health risks from radiation with baseline risks of cancer incidence or mortality, or with other personal or societal risks, for example, with risks from driving or smoking (Fig. 2).

Radiological risks estimates produced by scientists need to be weighted carefully by decision makers. For example, the decision to evacuate a populated area after a contamination with radioactivity may lead to adverse health effects and even deaths in elderly or hospitalized evacuees, to significant hardship for all evacuees, or to a social stigma for the affected area which is likely to have an economic impact. All these consequences may come as the price of avoiding a small radiation risk of cancer over the lifetime of the exposed population.

Glossary

Drone jamming Disrupting communications of a drone by interfering with the transmission of the communications signal.

Drone spoofing Remotely taking over a drone by deceiving the flight controller into using a false signal, most often a false GPS signal.

LiDAR (Light Detection And Ranging) A distance measuring method, similar to radar, using laser light reflecting off objects to measure the range between the sensor and objects.

Photogrammetry For 3D modeling and mapping, photogrammetry is a method of taking overlapping photos of an area and stitching the photos together to generate a larger model of the area being studied.

Introduction and general information

Background

Unmanned aerial vehicles (UAVs) have been used by militaries for decades. In 1916–17, the Hewitt–Sperry Automatic Airplane became the first demonstrated unmanned aircraft. Research for the aircraft was sponsored by the US Navy, which was interested in developing aerial torpedoes. These remotely controlled and automatic aircraft became precursors to the modern-day guided missiles. The first unmanned aircrafts that resemble modern-day UAVs with reconnaissance capabilities were first developed during the Cold War. During this time, the United States, the Soviet Union, the United Kingdom, Canada, and Israel all made major advancements in reconnaissance drone technology (Valavanis and Vachtsevanos, 2015).

The significant success of military UAVs and the rapid expansion of reconnaissance missions has led to the fast advancement of UAV technologies. These technologies first pioneered by militaries are now finding their way into civilian life. UAVs have only been used for applications within the civil environment in the past decade. In the United States, the Federal Aviation Administration began approving commercial civilian UAVs in 2013. UAV use by civilians is still a relatively new concept. The basic technologies are generally well developed because of military use; however, the technologies need to be adapted to specific civilian functions. Civilian UAVs have become useful tools in a broad variety of applications, such as surveillance, search and rescue, and agriculture monitoring. Existing technologies can also be modified for nuclear safeguards and security related tasks. These powerful and versatile machines can provide additional information to nuclear workers without putting the workers at any additional health or safety risks.

Advantages of civilian unmanned systems

Unmanned vehicles have numerous advantages for nuclear safeguards and security. A primary advantage is that radiological assessment tools no longer have to be constrained by the physical limitations of a team of nuclear workers. Instruments can be attached to unmanned vehicles and be transported to areas a human would generally not be able to access. Unmanned platforms can be equipped with payloads that perform a great number of useful tasks. Between unmanned rovers and unmanned aircraft, a wide variety of platforms exist for carrying various types of payloads.

UAVs represent a large and diverse category of aircraft, and they have become useful tools for a broad variety of applications and consequently can have very different appearances and capabilities. Their weights can range from less than a kilogram to more than a tonne; their costs can range from a few hundred dollars to millions of dollars; and their flight radii can range from a few meters to thousands of kilometers. Image processing systems, mapping systems, and sample collection systems are just a few of the items that can be integrated into UAVs to provide additional capabilities.

UAV tasks are commonly characterized by four D's: dull, dirty, dangerous, and deep. A mission with one of these characteristics is better suited to be completed by an unmanned system than a manned system:

- Dull—UAVs are well suited for low-workload, low-intensity tasks, such as automated takeoff and landing. Such tasks can be simply automated, often only requiring human oversight rather than direct and continuous control.
- Dirty—UAVs are ideal for environments where contamination is known or suspected. For such tasks, humans can remain in a clean environment, while UAVs are deployed into polluted spaces.
- Dangerous—A UAV is well suited to travel to any area too dangerous for a human. Inexpensive UAVs may be used sacrificially in high-risk areas.
- Deep—Heavy, high-flying UAVs are suited for long-range tasks. UAVs can carry instruments to far away locations so humans do not have to traverse the distance (Valavanis and Vachtsevanos, 2015; Tice, 1991).

With so much diversity between aircraft design and payload options, UAVs can be custom-built for any specific aerial task. A UAV's size is the primary determinant of what tasks it is capable of performing in an environment. Larger UAVs have the power capacity and function similar to manned aircraft and are capable of travelling great distances, transporting large payloads, and gathering high volumes of data over hundreds of kilometers of airspace. However, large aircraft are limited by their high production and maintenance costs, and they are not well suited for gathering data because of maneuverability issues. They cannot be used to gather data that is easily skewed by significant vibration or draft. Also, larger UAVs cannot move discretely or explore small areas, like building interiors. Smaller UAVs are much more capable of moving safely through environments filled with people and expensive property. Small UAVs, such as the ones covered in this report, can maneuver around a nuclear facility while the pilot stays safely on the ground. UAVs also have robotic persistence and can complete repetitive tasks in an exact manner each time, reducing the variations occurring due to human fatigue and error.

Unmanned vehicles can be used to inspect nuclear sites and monitor nuclear activities. Instruments can be attached to unmanned platforms and be transported to areas nuclear workers, such as safeguards inspectors and reactor operators, would typically be unable to reach. The following sections provide an overview of UAV capabilities and challenges that are most relevant to safeguards practices. For example, small UAVs can transport lightweight detectors into crowded industrial environments, or large UAVs can transport cameras and sensors high into the air.

Fig. 1 Flight path visualization for fixed-wing and rotary-wing UAV.

Basic UAV design

UAV designs employ two general types of airframes: fixed-wing and rotary-wing. Fixed-wing and rotary-wing aircraft are equipped to perform different types of tasks. The efficiency and longer flight time of fixed-wing UAVs makes them well equipped for outdoor, long-haul tasks. Rotary vehicles are better suited for indoor use and short-duration tasks. **Fig. 1** shows the difficulties of indoor use of fixed-wing UAVs. The vertical takeoff of rotary-wing vehicles is much better suited for confined spaces.

The fixed-wing UAVs require a long, runway-like area for takeoff and makes wide turns to orbit a specific area, whereas rotary-wing UAVs take off vertically and can make sharp horizontal movements (Abid et al., 2014). If a rotary-wing and a fixed-wing aircraft were in rooms of equal height, the fixed-wing aircraft would need a much wider room to properly maneuver. However, if the aircraft have the same weight and energy capacity, the fixed-wing aircraft would be able to fly longer.

Rotary-wing UAVs

Rotary-wing aircraft vary greatly in appearance. The smallest UAVs are no more than an inch in diameter—these are often called micro-air vehicles. The largest rotary UAVs are similar in shape and size to manned helicopters. Rotary aircraft fly using rotary blades that spin around a single mast called a *rotor*. Rotary UAVs can have single or multiple rotors, and their names usually refer to the number of rotors onboard the aircraft. For example, a UAV with four rotors is called a *quadcopter*, and a UAV with six rotors is a *hexacopter*. Two primary advantages of rotary aircraft are obstacle avoidance and safe collision.

Rotary-wing UAVs are able to slow down and hover in a fixed position. This characteristic allows rotary-wing UAVs to approach objects as slowly as desired, which makes it ideal for aerial monitoring of stationary or slow-moving objects. Because rotary-wing aircraft are able to maintain slower speeds, they are better capable of avoiding objects, an important feature when flying close to sensitive nuclear structures and equipment. Rotary-wing UAVs can also have their propellers guarded by bumpers or fenders that prevent the propellers from coming in contact with objects located nearby. Fenders can be as simple as curved rods that extend past the radius of the propellers. These only protect the propellers from objects in a UAV's horizontal flight path; consequently, expanding the fenders to form a cage around the UAV is a more robust safety option.

Rotary-wing design also has the advantage of vertical takeoff/landing. Vertical landing capabilities are ideal for small spaces and uneven terrain. Rotary aircraft can be used to hover and spin at a fixed point to achieve 360 degree panoramic scans of the interior or exterior of a nuclear facility. They can also be used outdoors to hover and take images of rooftops or dry cask storage areas.

Fixed-wing UAVs

There are fewer moving parts with fixed-wing UAVs, making design and maintenance easier. Fixed-wing UAVs can travel greater distances than rotary-wing aircraft with the same maximum takeoff weight. Fixed wings are also less sensitive to dangerous weather conditions, and they are more energy efficient than rotary wings, allowing fixed-wing aircraft to travel greater distances and stay in the air longer. Also, it is easier to collect air samples with fixed-wing aircraft because fluctuation in air flow around the aircraft is reduced.

One of the disadvantages of fixed-wing UAVs is that they require large open areas for runway-style takeoff and recovery. A fixed-wing UAV cannot rise vertically, hover, or immediately reverse directionality the way a rotary-wing UAV can. If both a fixed-wing and a rotary-wing UAV fly over an area and see something on the ground that must be revisited, a rotary UAV can simply reverse its direction to return to the area, whereas the fixed-wing UAV must make a wide turn to circle back to the area of interest. The operator of a fixed-wing aircraft must be familiar with fixed-wing flight dynamics, so these aircraft are not as easily controlled by novice operators.

Vertical takeoff and landing UAVs

Vertical takeoff and landing UAVs are a hybrid of fixed- and rotary-wing UAVs. These aircraft are able to takeoff, land, and hover just like rotary-wing aircraft; however, they can typically fly with greater energy efficiency than standard rotary-wing aircraft because they

possess wings similar to fixed-wing aircraft, which allow them to glide. In the air, vertical takeoff and landing UAVs typically maneuver like standard fixed-wing aircraft, but they do not require large open areas for runway-style takeoff and recovery.

Internal components

An unmanned aircraft has four electronic subsystems: power, communications, sensors, and computer. Most UAVs feature a single board computer onboard, and computer hardware comes preinstalled on most commercially available UAVs (Valavanis and Vachtsevanos, 2015).

UAV power

Although smaller UAVs do not have enough space for gas-powered engines, large and mid-size UAVs have sufficient space to include a gas propulsion power system. Smaller UAVs are most often battery powered and can have either one battery system for the entire UAV or two separate battery systems—one to power the UAV and one to power the payload. Some UAV designs have a separate power supply for the payload, so the aircraft's power supply is not diminished by addition of a payload.

UAV communication

The communication link is used to transfer information such as fuel data, electrical data, location, speed, propulsion, flight control, sensors, and data from the payload. In general, the system status requirements do not dominate the link; sensors usually dominate the link. There are many design constraints when choosing the proper communication system for a UAV: maximum distance of signal, allowed frequencies, number of UAVs and other devices operating within the network (too many devices can create noise and overcrowd the bandwidth), and frequency and magnitude of control messages (the compression factor of images and the rate information is refreshed affect the bandwidth needed). The diagram in Fig. 2 shows how information from an unmanned aircraft is translated to the user.

UAV sensors

With unmanned aircraft, sensors are particularly important. UAVs do not have the convenience of an onboard pilot's situational awareness or "sight sense." Good sensors are required so that UAV pilots can properly see and react to their surroundings. Sensors are valuable for two purposes: (1) improving the ease of operation and (2) improving the pilot's situational awareness. If improving the ease of operation for the pilot is the primary goal, increasing the number of sensors can increase the UAV's autonomy. Improving the onboard capabilities will free up bandwidth for other types of communication, such as real-time video transmission. If improving the pilot's situational awareness is the primary goal, increasing the number of sensors can increase the amount of information communicated to ground control. Improving the onboard capabilities can free up bandwidth for sensors to communicate.

The main types of UAV sensors are radar, laser, infrared, electro-optical, acoustic, and motion detection. Sensor systems can be divided into two categories: passive and active. Passive sensors detect energy (such as light and heat) that is naturally available. Active sensors provide the energy source that they detect when reflected by objects in the environment.

Technology review

UAVs are ideally suited to tasks that may enhance nuclear safeguards and security practices. These UAV tasks include monitoring structural changes of facilities by detecting changes in three-dimensional (3D) scans of interiors; searching for possible contamination inside a nuclear facility with radiological mapping; taking aerial images of rooftops and dry cask storage areas; creating 3D maps of mines and facility exteriors; and collecting environmental samples in dangerous or difficult-to-access places.

Imaging of nuclear facilities

In nuclear safeguards, design information verification involves the comparison of visual photographs. Two-dimensional images from previous inspections are compared to current inspection images, but some aspects of a facility may be difficult for an inspector

Fig. 2 Diagram of typical components found within the UAV communications structure.

to properly photograph. By sending UAVs into high-up, very tight or otherwise difficult-to-access places, inspectors can stay stationary and reduce chances of slips, falls, or overexertion. While inspectors control the aircraft from the ground floor, the UAV can provide inspectors a bird's-eye view of machines and structures. Furthermore, UAVs can fly around large objects to capture features at different angles. Some parts of a facility may be too far or small for inspectors to photograph with clear resolution. However small, collision-tolerant UAVs are capable of carrying cameras into crowded environments to take close-up images of the objects an inspector cannot reach.

3D mapping of facility interiors

Rotary-wing unmanned aircraft can be used for 3D mapping of facility interiors. Currently, nuclear facility operators and inspectors set up a 3D imaging system on the floor of a facility or carry a system throughout a facility (Juchmann, 2015; Nuclear Decommissioning Authority, 2014). However, a UAV can carry the system high into the air to gain an additional perspective of the facility. Additionally, a UAV can autonomously move around the facility to generate a complete 3D map while the inspector monitors the process, either in or outside the facility. The quality of a scan will depend upon the speed of the UAV and the amount of time the UAV is allotted to doing the scan.

LiDAR 3D mapping is already used in the aviation industry for automated aircraft inspection. This autonomous mapping can detect damage from hailstones or lightning, and even normal wear and tear. The same technique can be applied to pipes, walls, and machines in nuclear facilities. 3D scans generated during routine inspections of a nuclear facility could be used to track any changes made to the facility's structure. Spectral graph theory, a mathematical method for identifying and studying significant features of graphs, can be used to quantify the variance between 3D scans to help inspectors determine when two scans differ beyond the UAV device's standard amount of deviation. Although the 3D indoor imaging has already been proven useful for inspections, radiation contamination maps can be laid over 3D point clouds of nuclear facilities to provide greater awareness of contamination locations (Martin et al., 2016). In this technique, each point in the 3D map of the facility is given a value indicating the level of radiation present at each point. This technology was used to measure radiation levels in the damaged reactors of Japan's Fukushima Daiichi nuclear power plant.

3D mapping of facility exteriors

For nuclear safeguards, the International Atomic Energy Agency (IAEA) uses high resolution (< 1 m) satellite imagery (Johnson et al., 2015). With satellites, IAEA inspectors can verify additional protocol delegations and design information. However, some nations have resolution limits on commercial imagery from satellites. For example, the US Department of Commerce only relaxed restrictions on commercial satellite imagery in 2014. Previously, the Department of Commerce only allowed satellite companies to sell to customers imagery with 50 cm resolution, but now the department allows satellite companies to provide imagery with up to 25 cm resolution.

In a 2007 international safeguards project, aerial photographs were used to construct a map key (with parameters such as fences, buildings, and their relationships to each other) of a nuclear facility that was used to identify features in satellite images with resolutions between 0.61 and 1 m (Jasani et al., 2007). Aerial photographs are required to identify facility features that are difficult to identify using a satellite. Periodically collecting high definition aerial images of facilities helps inspectors track facility changes observed during the continuous satellite monitoring. Lightweight unmanned aircraft would be able to generate imagery for these map keys in a much less intrusive manner than manned aircraft.

Sample collection

Current nuclear safeguards processes involve swipe sampling at nuclear facilities. As part of the IAEA's standard processes, swipe sampling is performed regularly by swiping various surfaces of a nuclear facility. However, environmental sampling can be used for many nuclear activities beyond safeguards verification, including environmental monitoring and emergency response.

Environmental sampling is not a novel concept, but combining the process with unmanned vehicles for nuclear security and safeguards purposes is an emerging area of research. When using unmanned vehicles, environmental samples can be collected in areas with untraversable terrain, rooftops and platforms only reachable by ladders, areas with low lighting or view-obstructing smoke, or areas suspected of chemical or radiological contamination. Collected samples can be (1) transported back to the ground station for analyzation or (2) processed in situ by an analyzer onboard the aircraft. The diagram in Fig. 3 shows typical components found in simple sampling systems. In this example, particles are deposited in a collector to be analyzed at a later time. The

Fig. 3 Diagram of typical components in a mobile sample collection system.

portability of the air sampler, the analyzer, and the necessary pumps and tubing will depend on the types of particles needing to be detected and the predicted minimum detectable quantity. Unmanned vehicles can help nuclear workers collect samples in the air, soil, or water.

Air sampling

Lightweight and handheld air sampling technologies can be adapted to function onboard an unmanned vehicle. Typically, unmanned air sampling is conducted using a UAV, which enables sample collection to occur virtually anywhere in the air. Active and passive samplers can be used onboard UAVs. Active sampling involves using a pump to pull air through the collector. Passive samplers can collect samples from static air or take advantage of the motion of the aircraft to move air through the collector.

Air sampling can be used for environmental monitoring or emergency response. It is often impractical to set up a dense network of permanent sampling stations at a nuclear facility, so a mobile solution is often preferred. During emergencies, such as a radiological release, unmanned systems can be deployed to track and analyze plumes.

Unmanned aircraft are well suited for air sampling and possess many advantages over manned aircraft. During emergencies, such as a radiological release, unmanned aircraft can be quickly deployed. UAVs are typically smaller than manned aircraft and can be more easily transported to the site of the incident. Operating an unmanned aircraft typically requires less training than operating manned aircraft; therefore, training an entire incident response team to pilot unmanned aircrafts is significantly easier than piloting manned aircrafts. The costs of UAVs are significantly lower than manned aircraft, so an incident response team can purchase and deploy multiple unmanned aircraft for the cost of one manned aircraft.

Soil and water sampling

Soil and water sampling can also be conducted onboard unmanned vehicles. When samples need to be collected from areas deemed inaccessible to humans, unmanned aircraft and rovers can be used to transport sample collection equipment to the inaccessible environments. When collecting samples in the field, the robotic persistence of unmanned systems is advantageous when samples need to be collected from an exact location multiple times.

For soil sampling, unmanned vehicles can be equipped with payloads that collect particles from the surface of the soil. Simple collection techniques involve using a wipe, swab, or adhesive that makes contact with the soil surface. More advanced techniques involve using a heated probe to vaporize the surface of the soil and using a pump to pull the vaporized particles into the collection device. Water sampling techniques also involve using a pump to pull fluid into an onboard collection system.

Safety and security risks

Safety problems concerning unmanned systems

Unpredictable situations can cause unmanned systems to fail and create risks to the people and property around them. Unmanned vehicles can cause serious bodily harm. Even small UAVs can cause personal injuries by cutting people with their rotors or causing a blunt force trauma by crashing at high speeds. In terms of property damage, UAVs can crash into and break windows, dent pipes, or fall into and clog ducts. UAV retrieval is a potential safety issue as well. For example, a UAV could become stuck in an area where it is too dangerous for a human to retrieve it, such as an area with high levels of radiological contamination. Catastrophic failure causes the most apparent safety risks, yet any situation that prevents a UAV from completing its intended mission can result in a safety risk. Unmanned system mission failure can be caused by an assortment of circumstances including poor weather conditions, mechanical failure, operator error, or an attack.

Weather conditions

Some smaller UAVs are not built to withstand high winds or other strong weather conditions. Other UAVs are structurally capable of withstanding the weather but are designed and certified only for visual operation. For these aircraft, poor weather conditions may prevent the operator from keeping sight of the aircraft during the entire mission. Operating procedures should be adopted to ensure UAVs are not deployed in conditions that could create an unreasonable safety risk for people or property.

Mechanical failure

A UAV mechanical failure does not have to be catastrophic to cause a safety problem. Any failure that causes the UAV to abort a mission can pose a safety risk. For example, the failure of the GPS system while out of the operator's sight could cause the UAV to fly into a dangerous area. The likelihood of mechanical failure can be prevented by proper reliability and maintainability practices. Vital parts of the aircraft should be monitored for integrity. If components of a system are not considered highly reliable individually, the system's reliability can be improved by adding component redundancy. Although precautions such as these can make UAVs highly reliable, risk of failure cannot be completely eliminated.

Operator error

This category of UAV mission failure is virtually boundless. Good training will prevent ignorance and prevent causes of carelessness and uncontrollable conditions. Training programs reduce chances of operator error, but the risk of human error is always present

and unpredictable. Human error is the primary cause of 17% of unmanned mishaps; however, it is the cause of 85% of manned mishaps (Hart et al., 2013).

Operational accidents could be caused by ignorance, carelessness, or uncontrollable conditions. A poorly trained operator may be ignorant about proper flight rules or unaware they cannot fully control the UAV. Alternately, an operator may be knowledgeable but still choose to operate the vehicle in an unsafe manner. For example, an operator could intentionally ignore training and disobey guidelines. Finally, an operator may be working in an environment that makes it difficult to fully control the unmanned vehicle. Hectic environments and exhaustion can easily cause forgetfulness and poor judgment, leading to errors.

Attack

Many UAV attacks are premeditated by well-trained individuals and executed using high-tech equipment. Highly technical attacks could be physical in nature and be designed to down/destroy a UAV with a weapon, or the attack could be a form of cyber warfare. Hacking an unmanned vehicle's communication system and seizing control of the aircraft while it is flying, called *spoofing*, is a major safety concern. Once an attacker has control of the UAV, the UAV could be intentionally crashed or flown to a dangerous area. Attacks are not always carried out by people with specific intentions or strong motives. An attack could be done by fearful bystanders that are unaware of the UAV's nature or mission. Even wild animals, such as hawks, can attack UAVs (NBC, 2014).

Security problems concerning unmanned systems

United States Code 44 USC §3542 defines information security as "The means of protecting information and information systems from unauthorized access, use, disclosure, disruption, modification, or destruction in order to provide integrity, confidentiality and availability." NATO (North Atlantic Treaty Organization) Cooperative Cyber Defence Centre of Excellence describes UAVs as "highly exposed technical systems" that are "highly dependent on external input" (IAEA, 2014). UAV communications are difficult to secure because they require multiple wireless input channels to manage all external inputs. Information onboard a UAV can be compromised in many ways. For example, data confidentiality could be compromised by eavesdropping (loss of data confidentiality), jamming, and spoofing.

Small UAVs are less dangerous than manned aircraft. If a catastrophic failure occurs, a pilot stationed at ground control is much safer than a pilot onboard an aircraft. Unpredictable situations can cause UAVs to fail and create risks to the people and property around them. UAV mission failures include causes such as dangerous environments (e.g., poor weather, high levels of radiation), mechanical failure, and physical attacks on the aircraft and operator error, which are all similar to the primary mission failures of manned aircraft. However, there is one cause of failure that is more likely to occur with unmanned aircraft than manned aircraft: cyberattack.

UAV cyberattacks can be premeditated by well-trained individuals and completed using high-tech equipment. Eavesdropping and spoofing are the two main security problems. Hackers access the communication system and observe the information being transferred between the UAV and ground control. In a spoofing attack, cyberattackers seize control of the UAV in flight and guide it to a specific area or intentionally crash it. When examining a UAV's susceptibility to cyberattacks, a nuclear worker must consider a UAV's frequency spectrum, robustness of the "sense and avoid" software, data link issues for communication and surveillance, and separation minima.

Eavesdropping

Attackers can access the UAV's information by eavesdropping between the sensors and onboard computer or between the onboard computer and ground control. Environmental conditions such as landscape, weather conditions, and flying altitude can affect the integrity of a UAV's secured connection. Tactics such as encryption and tunneling protocol can reduce the risk of eavesdropping. Digital signatures and forgery detection also improve the integrity of data security. Encryption hides transmitted data, but forgery detection will prevent data from being manipulated or overwritten by a non-valid signature (ICAO, 2006).

Jamming and spoofing

In 2011, the US Department of Homeland Security funded a University of Texas research team, which successfully hacked a Department of Homeland Security drone using jamming and spoofing. The UAV's secure connection to ground control was first compromised by jamming, and then a spoofing technique was used to generate a counterfeit GPS signal to commandeer the UAV. The Department of Homeland Security was motivated to do this research after Iranians claimed to take down an American drone using spoofing. Iran claims it was able to jam communications between operators and the aircraft, take control of the UAV, and guide it to a new destination. The Iranians then landed and seized the UAV to inspect its components (Kerns et al., 2014).

A spoofing attack puts control of the UAV directly in the hands of the attacker. Once in the hands of the attacker, the UAV can be broken down, encryptions can be disabled, and the attacker has unlimited time to study and reverse engineer the UAV. Spoof detection and prevention tactics such as frequency unlock monitoring and jamming-to-noise monitoring are being studied, but spoofing attacks are still a threat. A 2014 paper published by the same Texas research team states, "To the best of our knowledge, all modern commercial civil GPS receivers, even those that provide high-integrity measurements, are vulnerable to civil GPS spoofing" (Federal Aviation Administration, 2015).

Conclusion

The unmanned technologies described in this section were selected based on commercial availability, reliability, and ease of use. The first technology described was two-dimensional imaging of confined spaces, which can be performed by collision-tolerant, rotary-wing UAVs that take visual and thermal images of nuclear facilities from difficult-to-access areas. Instead of having inspectors or reactor operators climb ladders to take images of tall equipment and ceiling pipes, UAVs can travel to these poorly accessible areas while the worker remains stationary.

The second technology introduced was 3D mapping of facility interiors. This task can be completed by autonomous, rotary-wing UAVs that have 3D mapping technology that can generate 3D point-cloud maps of facilities. The third technology, 3D imaging of facility exteriors, can be performed by rotary- and fixed-wing UAVs that are suited for outdoor use and also have 3D imaging technology. UAVs used for 3D mapping of facility exteriors can give inspectors better resolution than commercial satellites. In addition to these imaging technologies, rotary- and fixed-wing UAVs can carry air sampling systems in their payload, allowing inspectors to take an air sample virtually anywhere in the air.

Unmanned systems are technically capable of enhancing current nuclear safeguards and security practices. Although there are many advantages to using unmanned systems for safeguards purposes, there are some concerns that need to be addressed. Unmanned systems will need to overcome a series of institutional obstacles before they can be deployed in the field.

A brief description of boron neutron capture therapy

This article provides an illustrative example of microdosimetry as it applies to boron neutron capture therapy (BNCT). BNCT is chosen as an example application of microdosimetry because it demonstrates calculation of doses dependent of the distribution of a particular molecule, in this case molecules that have ^{10}B as a component. Additionally, BNCT causes different doses to the cellular nuclei, the cellular cytoplasm, and to the interstitial space (volumes outside of cells but still within the organism). This example is based on the original work of BNCT researchers who attacked the most common primary brain tumor, glioblastoma multiforme. This is a devastating, deadly malignancy. Finally, this contribution is adapted from the doctoral dissertation and papers of the author (Kabalka et al., 2003; Nichols, 2008; Nichols et al., 2002, 2009). In the 1990s, there were BNCT clinical trials for glioblastoma multiforme conducted at Harvard Medical School that used the Massachusetts Institute of Technology's reactor and the Brookhaven National Laboratory's Brookhaven Medical Research Reactor. Dr. Nichols sent glioblastoma patients to both centers and managed them medically pre- and post-BNCT providing the most trial participants outside of the two centers themselves.

After James Chadwick's discovery of the neutron in 1932 (Chadwick, 1932), Maurice Goldhaber collaborated with Chadwick (Chadwick and Goldhaber, 1935), Taylor (Taylor and Goldhaber, 1935), and Burcham (Burcham and Goldhaber, 1936) to study slow-neutron bombardment of the stable isotopes of boron, lithium, and nitrogen. They found that the tracks from the disintegration of boron-10 were two short straight segments consistent with two heavy charged particles. The average range of the particles was found to be $\sim 8\text{ }\mu\text{m}$ in the photographic emulsion. Results obtained by these researchers would show that the actual reaction could be represented as two reaction channels:

where $^{11}\text{B}^*$ represents a metastable state that decays immediately by the two reaction channels as shown above and the probability of the reaction channel is above the arrow.

Boron neutron capture therapy (BNCT) was first proposed in 1936 by the German biophysicist, G.L. Locher, as a potential cancer therapy the same year that Taylor and Goldhaber described the $^{10}\text{B}(\text{n},\alpha)^7\text{Li}$ reaction (Locher, 1936). Locher had examined the theoretical biological effects of these particles and realized the therapeutic potential for cancer therapy. Part of the attractiveness of this idea is that ^{10}B has a large cross-section at 3840 b for low-energy neutrons ($\sim 0.025\text{ eV}$) relative to other isotopes found in human tissues. Additionally, ^{10}B is stable and even in large doses is non-toxic to humans.

Although much research was accomplished in the subsequent years, the first human trials did not occur until two decades later. Conger and Giles at Oak Ridge National Laboratory (Conger and Giles, 1950) demonstrated the deoxyribo-nucleic acid (DNA) damage from the (n,α) reaction in lily bulbs containing boron when exposed to a beam of thermal neutrons. This inspired neurosurgeon William Sweet and others at the Harvard University Medical School (HMS), Massachusetts General Hospital (MGH), the Massachusetts Institute of Technology (MIT), and the Brookhaven National Laboratory (BNL) (Sweet, 1997). The Brookhaven Medical Research Reactor (BMRR) was constructed expressly for BNCT and contained a full clinical facility for onsite hospital

care. An excellent review of the early work in BNCT at HMS/MIT and BNL may be found in an article written by Sweet (1997). As a neurosurgeon, Sweet wanted to treat the deadly, aggressive, and most common primary brain malignancy: glioblastoma multiforme.

Glioblastoma multiforme (GBM) is truly a horrific killer that recognizes no socio-economic factors, age group, race, or border (Wilson et al., 1991). It arises from the brain's supportive astrocytoma cells and is known as a high grade or Grade III (or IV in some grading systems) astrocytoma (Burger et al., 1988; Daumas-Duport et al., 1988; Escourolle and Poirier, 1978). The tumor is infiltrative in nature, which means that it extends by thin small streams of invasive cells analogous to the roots of a plant that infiltrate the soil. Glioblastomas are often quite large before symptoms occur. The presentation of a GBM might be a fall, seizure, or subtle change in speech (Wilson et al., 1991). Glioblastomas have some cells that undergo an amoeboid-like transition where the cells 'swim' through the brain to distant locations. The cells that undergo an 'amoeboid phase' have been called infiltrative tumor cells (ITC) (Daumas-Duport et al., 1987) and account for the failure of all attempts by all modalities (chemotherapy, surgery, radiation and combinations of these) to achieve long term survival. This 'amoeboid phase' is the reason that performing a hemispherectomy were uniformly unsuccessful (Daumas-Duport et al., 1983, 1982, 1987; Demuth and Berens, 2004; Kelly et al., 1987).

There are no known risk factors or genetic links to the development of GBM (Escourolle and Poirier, 1978). The risk of developing a GBM is proportional to age until the latter years when the risk grows faster than age (Wilson et al., 1991). In the 1950s the median life expectancy after the diagnosis of GBM was about 21 weeks. Nearly 70 years later, a 2017 review of therapies for GBM states a survival of only 8–15 months (Anjum et al., 2017). The course of the disease is progressive deterioration despite aggressive therapy so that the patient spends their most functional time going for treatments that makes them ill. The time following the patient's therapy is characterized by a low functional status prior to inevitable death. Thus, there has been little improvement in the past 70 years in the quality of life for the glioblastoma multiforme patient despite a modest increase in life expectancy. Most strategies begin with debulking surgery followed by radiation and/or chemotherapy. Traditional photon beam radiotherapy is about 40 treatments. BNCT delivers a larger total dose to the tumor and is only a single dose that usually has only very mild side effects (Barth et al., 2005; Busse et al., 2003; Coderre et al., 1998; Coderre and Morris, 1999; Diaz et al., 2000). BNCT provides a better quality of life than other radiotherapies but has not fulfilled its promise as described in the excellent review by Moss (2014). BNCT has been extended to other cancers in the past two decades with some most encouraging results in some such as melanoma (Suzuki, 2020).

Modelling the human cell

Cells in human tissues have irregular shapes and vary in size from a sperm cell of about $30 \mu\text{m}^3$ to nerves whose cell body lies in the spinal cord and innervate muscles in the toes. A good approximation of a 'typical' human cell is about $1000 \mu\text{m}^3$ which is a sphere of about 5 or 6 μm in diameter. It is better to approximate a cell as an ellipsoid as few cells are actual spheres. An ellipsoid may be defined by axes a , b , and c , as is common in nuclear physics (Jelley, 1990) for the atomic nucleus by an eccentricity, ϵ , so that:

$$a = b = \frac{r}{\sqrt{1 + \epsilon}}$$

and

$$c = r(1 + \epsilon)$$

where the volume, V , is given by:

$$V = \frac{4\pi}{3}abc = r^3$$

where r is the radius of a sphere of the same volume as the ellipsoid. Thus, when ϵ equals zero, the ellipsoid is a sphere with $a = b = c$. For $\epsilon > 1$, as ϵ increases, the ellipsoid becomes more elongated (football shaped) which is termed prolate while eccentricities in the range $-1 < \epsilon < 0$ lead to a flattened (pancake) shape which is termed oblate. Cells used in the calculations will be ellipsoids with the nucleus also being an ellipsoid that is entirely within the ellipsoid cell. All ellipsoids are defined as above with an eccentricity, but nuclei and cells do not have to have the same centroid. The nuclear boundary and cellular boundary can touch at a single point or circumferentially. Likewise, the ellipsoidal cells are arranged in a face centered cubic and can have a cell edge to edge separation from zero (touching) or as large as desired.

The cell modelling defines three regions. The first is the volume inside the ellipsoidal nuclei of the cells. Next is the volume inside the ellipsoidal cell minus the nuclear volume which defines the cytoplasm of the cell. Finally, the space outside of cells is called the interstitium and is the volume in a cuboid defined by the outer edges of the cells. As the volume of the cells grow and their edge-to-edge separation increases, the interstitial volume increases.

Other codes calculate the energy deposited in the nuclei, cytoplasm, and interstitium for user supplied concentrations of ^{10}B . The ^{10}B distribution in a volume is uniform though concentration is defined by the region where the boron has an interaction. For example, there could be 100 ppm in all nuclei, 50 ppm in all cytoplasm, and 5 ppm in the interstitium, but the distribution within each volume is uniform. The energy deposition is calculated for each region and then converted to doses to match clinically meaningful calculations.

Finally, for historical reasons, BNCT was originally studied in the most common primary brain malignancy, glioblastoma multi-forme (GBM). It is a very difficult malignancy to treat since it undergoes an amoeboid phase where tumor cells essentially ‘swim’ through brain. Consequently, isolated tumor cells surrounded by entirely normal tissue and the main tumor must be destroyed. It is these distant cells that are responsible for recurrence in traditional photon beam radiotherapy. BNCT holds promise if the tumor preferentially concentrates a boron-10 carrier molecule far more avidly than normal tissue. More recently, BNCT is being used with other malignancies with success (Suzuki, 2020). A good boron carrier though not ideal in the sense of very large preferential concentrations is the boronated essential amino—boronophenylalanine (BPA) that is entirely nontoxic and safe even in very high doses.

Characteristics of neutron beams for BNCT

Until recent years, accelerator sources for epithermal neutron beams were not able to deliver a sufficient neutron flux for BNCT in a time in which a patient could remain relatively motionless without sedation (a few tens of minutes). BNCT is based on the large absorption cross section of ^{10}B for thermal neutrons, i.e. neutrons with energies < 1 eV but with most ~ 0.025 eV (which is of the mean energy in a Maxwell–Boltzmann distribution of thermal neutrons) so it is necessary for neutron energies to be in the thermal range at the depth of the tumor in the human body. Many tumors of interest do not occur on the surface so techniques were developed to treat deep-seated tumors.

The technique used is to employ epithermal neutron beams as those developed at the MIT reactor (MITR) and the Brookhaven Medical Research Reactor (BMRR). These reactor facilities utilized filters (materials design to slow-down the source neutrons and optimize the spectrum of the neutron beam that impinges on the brain) to deliver neutrons with sufficiently high epi-thermal energy to penetrate several centimeters of tissue before slowing to thermal energies. Accelerator based neutron sources (often referred to AB-BNCT) are now capable of obtaining minimal acceptable epi-thermal neutron flux of $\geq 10^9$ n/cm²/s required for BNCT. Additionally, it is possible to adjust AB-BNCT systems so that the epi-thermal neutron energy spectrum will maximize thermal neutron flux at the tumor location in the body (Greenspan and Kani, 1998, 2001).

The distance traveled in tissue by an epithermal neutron may be estimated by assuming that each interaction is dominated by n-p scattering. For low energy n-p reactions, the scattering is predominately elastic which allows evaluation by the classically derived relation:

$$E_p = \frac{1}{2}E_n(1 - \cos\phi)$$

where ϕ is the center of mass scattering angle, E_n is the energy of the incident neutron, E_p is the energy of the recoil proton, and the mass of the proton and neutron have been taken to be equal, which is sufficiently accurate for this calculation. On average, the neutron losses $\frac{1}{2}$ of its kinetic energy in each collision with the proton in a hydrogen atom when E_n is $> \sim 0.05$ eV (at lower energies the neutron energy loss is smaller since the thermal motion of the target protons needs to be taken into account). Thus,

$$E_p = \frac{1}{2}E_n.$$

For an initial neutron energy of E_i that undergoes n collisions, the final average energy, E_f , is approximately:

$$E_i \left(\frac{1}{2}\right)^n = E_f$$

or solving for n :

$$n = \ln^{-1} \left(\frac{1}{2}\right) \ln \left(\frac{E_f}{E_i}\right)$$

For neutrons of initial energy $E_i = 10$ keV to be reduced to an energy of $E_f = 0.025$ eV, approximately 19 collisions are required. For comparison, approximately 5 collisions are required if the initial energy is 1 eV. The mean free path of a neutron—the average distance the neutron travels between collisions, λ , may be approximated from the macroscopic elastic cross section (product of the scattering cross-section with constituent $i - \sigma_i$, and the number densities, N_i , of the target constituent i) by:

$$\lambda = \left(\sum_i N_i \sigma_i \right)^{-1}.$$

Table 1 shows typical elemental abundance of light elements along with the corresponding number densities, elastic scattering cross sections, number density-elastic cross section products (macroscopic cross sections). By the above equation, the mean free path of a neutron (in tissue) with an energy of 0.025 eV is:

$$\lambda = 0.46 \text{ cm}$$

Using the same calculations, Table 2 contains the mean free path as a function of initial epithermal neutron energy. Using a typical value for the mean free path of 0.67 cm (for an epithermal neutron with an initial energy of 10 keV) neutrons will travel

Table 1 Typical tissue elemental abundance, number density, and elastic scattering cross section.

Element	Percent abundance	Atomic weight	Number density (cm^{-3})	σ (b)	$N\sigma$ (cm^{-1})
H	0.11	1.008	$6.51\text{E}+22$	30.39	1.977084

Table 2 Mean free path, λ , for different epithermal neutron energies.

E_i (eV)	$N\sigma$ (cm^{-1})	λ (cm)
1	1.5131	0.66091
10	1.4939	0.66937
100	1.4919	0.67031
1000	1.4846	0.67356
10,000	1.4277	0.70043

~ 12 cm prior to reaching a thermal energy, while neutrons with an initial energies of 1 eV will travel ~ 3.4 cm before they are thermalized. Since the neutrons scatter in random directions, (in the center of mass coordinate system) the total distance traveled is not a straight line. The multiple scattering reactions result in neutrons having momenta vectors with random directions especially on the scale of microdosimetry calculations ($< \sim 150$ μm). Using phantoms at reactors involved in previous BNCT trials, the epithermal neutron flux was nearly totally thermalized at a depth in a phantom of ~ 10 cm (Coderre and Morris, 1999). Typical tumor depths are of a few centimeters so that an epithermal neutron beam will be thermalized close to their location. The important implication for microdosimetry is that, with the exception of superficial tumors, there is no preferred direction of the thermal neutrons a few cm into tissues making the probability of a $^{10}\text{B}(\text{n,p})^7\text{Li}$ reaction dependent only upon the distribution of ^{10}B in the region of interest.

Contributions to the microscopic dose

The goal of a neutron source is to produce a neutron beam with a relatively flat energy distribution in the epithermal range as discussed above. Reactor neutron sources will have some γ -ray contamination where the intensity and neutron energy spectrum are dependent on the details of the particular reactor and filters employed. These contaminants to the epithermal beam are not considered in this article because they are installation dependent and the application of BNCT has progressed to accelerator sources. Most AB-BNCT utilize the $^7\text{Li}(\text{p,n})^7\text{Be}$ or the $^9\text{Be}(\text{p,n})^9\text{B}$ reactions as a source of neutrons that have no γ -ray channels (Naito, 2018).

The major sources of the radiation dose from the neutron interactions with tissue are the reaction products from the ^{10}B reaction, i.e. the alpha particles, the lithium nuclei, and the γ -ray. Additional components in the radiation milieu are the proton produced in the nitrogen (n,p) reaction. Recoil protons produced when neutrons elastically scatter from hydrogen atoms attached to organic molecules can also contribute to the dose and will also be considered. Also, hydrogen has a non-negligible cross section for neutron capture that results in deuterium and a γ -ray. Since hydrogen is in all organic molecules, this contribution to the dose will also be considered. The cross sections for other reactions, or the number density, are sufficiently small that other reactions are not considered (Nigg, 1994; Nigg et al., 1991; Raaijmakers et al., 1997, 1995).

The dose from the $^{10}\text{B}(\text{n},\alpha)^7\text{Li}$ and $^{10}\text{B}(\text{n},\alpha\gamma)^7\text{Li}$ reactions

Barth, Soloway, et al. report that if the boron concentration in the tumor is 20–40 $\mu\text{g/g}$ of tissue (10^9 ^{10}B atoms/cell) then 75–80% of the radiation dose arises from the $^{10}\text{B}(\text{n},\alpha)^7\text{Li}$ and $^{10}\text{B}(\text{n},\alpha\gamma)^7\text{Li}$ reactions (Soloway et al., 1997). Other reactions such as the recoil protons in hydrogen scattered by the incident neutrons and the γ -ray from the ^{10}B reaction make up the majority of the remaining dose. Some components that are important to the dose delivered to the tumor and normal tissue are of a lesser significance in understanding of the microdosimetry due to their low magnitude or lack of significant microscopic spatial variation.

Begin with the dose from the ions produced in BNCT:

and

The heavy ions above are charged to the 2+ state for the alpha particle and 3+ state for the lithium nucleus. These highly charged ions have relatively short ranges in matter, but the high charge states interact with the electron clouds and atomic nuclei of surrounding molecules by Coulomb interactions resulting in rapidly slowing down that deposits all the energy from the disintegration of the metastable ${}^{11}\text{B}$ that decays immediately ($t_{1/2} \sim 10^{-12}$ s) (Wang, 2006). The ranges of the ions shown in Table 3 were generated by the online code SRIM2008 at www.srim.org. As noted above, the short ranges are beneficial because the ions travel on the order of a cell diameter depositing their entire energy so that the majority of the dose occurs wherever there are ${}^{10}\text{B}$ atoms. Thus, a cell may have the entire energy from the ${}^{10}\text{B}(\text{n},\alpha){}^7\text{Li}$ reaction (~ 2.34 MeV) deposited within its volume. The Coulomb interactions with the molecules along ion paths produce short-lived free radicals that significantly damage other molecules. Any ion paths through or near the cellular nucleus can result in major damage to the DNA from two mechanisms. The first is due to direct damage by the heavy doubly or triply charged ions resulting in double strand DNA breaks which the cell is less able to repair than single strand breaks. The second mechanism is from free radical formation, which also cause significant DNA damages. DNA damage leads to the cell no longer being able to synthesize critical molecules that leads to a loss of homeostasis that leads to cell death. Traditional photon beam radiation damages cells by free radical formation so that the combination of free radicals and direct damage by the heavy ions is much more effective at killing tumor cells than in the case with photon irradiation. Therefore, the efficacy of BNCT is dependent upon the local boron concentration (Barth and Soloway, 1997). Nearby normal cells or tumor cells in the G_0 (resting) phase of the cell cycle will not accumulate the boronated carrier molecule as avidly as tumor cells and will receive a smaller radiation dose than the active tumor cells where the boronated carrier molecule concentrates. The ${}^{10}\text{B}(\text{n},\alpha){}^7\text{Li}$ and ${}^{10}\text{B}(\text{n},\alpha\gamma){}^7\text{Li}$ reactions are responsible for about 80% of the total macroscopic dose and are responsible for most of the variability due to the variation in ${}^{10}\text{B}$ distribution (Barth and Soloway, 1997).

The ${}^{14}\text{N}(\text{n},\text{p}){}^{14}\text{C}$ reaction

Nitrogen is a common element in all human tissues and the ${}^{14}\text{N}(\text{n},\text{p}){}^{14}\text{C}$ reaction produces a significant portion to BNCT dose. The nitrogen capture reaction is:

which occurs in all tissues where there is a neutron flux. The proton carries the majority of the 0.59 MeV and deposits its kinetic energy in a range of $\sim 10.5\ \mu\text{m}$ in human tissue as determined by SRIM2008. The distribution of nitrogen is not entirely homogeneous for different cell types where the concentration is higher in protein rich cells, as opposed to lipid laden tissues, but the heterogeneity is small except for adipose tissue. Even adipose cells have cellular architecture with proteins so that the in vivo heterogeneity is not significant for most tissues and in particular for tumors that rarely have lipid laden cells (except for the rare liposarcoma). No studies describing the nitrogen distribution on a cellular or sub-cellular level have been found by my literature survey to date, and nitrogen is ubiquitous in all tissues. Thus, the nitrogen distribution is modeled as homogeneous. If the nitrogen distribution is homogeneous, the contribution to the total dose from the ${}^{14}\text{N}(\text{n},\text{p}){}^{14}\text{C}$ reaction will be small and additive. This may be shown by plotting the dose for spherical cells of radii $r_c = 4.0\ \mu\text{m}$ with nuclei of radii $r_n = 3.0\ \mu\text{m}$ that are plotted as a function of the edge-to-edge separation of the cells in a body centered cubic. The ${}^{10}\text{B}$ concentrations are modeled as 10 ppm, 50 ppm, and 50 ppm in the interstitium, cytoplasm, and nuclei respectively, which is consistent with experimentally determined values (Coderre et al., 1998; Coderre and Morris, 1999; Elowitz et al., 1998). Fig. 1 contains the doses from the ${}^{14}\text{N}(\text{n},\text{p}){}^{14}\text{C}$ contribution whereas Fig. 2 depicts doses without the proton dose. As the edge-to-edge separation between the cells increases, the dose to the nuclei and cytoplasm decreases which is because there is less dose from neighboring cells because the short range of the boron reaction products is less likely to go from the periphery of one cell to a neighbor. Likewise, the volume of the interstitium receiving a dose from a cellular source remains nearly constant (when cells are close together, some of the ion tracks will go from one cell to another, but the effect falls off rapidly as seen by the dose to the cell nucleus). As the cellular separation increases, the percentage of the interstitial volume receiving a dose originating inside of a cell decreases. These effects and the implications for the efficacy of treatment will be discussed further in subsequent sections.

Table 3 Range of BNCT associated ions in human tissue.

<i>Ion</i>	<i>Atomic number</i>	<i>Atomic mass</i>	<i>Initial energy (keV)</i>	<i>Range (μm)</i>
H	1	1.008	590	10.52
He γ	2	4.003	1470	7.39
He	2	4.003	1780	9.06
Li γ	3	7.016	840	3.93
Li	3	7.016	1010	4.38

Fig. 1 Dose versus cell edge to edge separation for spherical cells of radius $r_c = 4.0 \mu\text{m}$, nuclei of radius $r_n = 3.0 \mu\text{m}$, and eccentricity of $\epsilon = 0$ for boron concentrations of 10 ppm in the interstitium, 50 ppm in the cytoplasm, and 50 ppm in the nuclei. Dose includes contributions from the boron (n,α) and nitrogen (n,p) reactions.

Fig. 2 Dose versus cell edge to edge separation for spherical cells of radius $r_c = 4.0 \mu\text{m}$, nuclei of radius $r_n = 3.0 \mu\text{m}$, and eccentricity of $\epsilon = 0$ for boron concentrations of 10 ppm in the interstitium, 50 ppm in the cytoplasm, and 50 ppm in the nuclei. The dose includes contributions only from the boron (n,α) reaction.

The destruction of the nucleus is generally considered the goal of radiation therapy. **Fig. 3** contains the nuclear dose (dose to the nucleus) as a function of cell edge to edge separation for both cases, i.e. with and without the dose from the $^{14}\text{N}(\text{n,p})^{14}\text{C}$ reaction. The nuclear dose curves (with and without the contribution for nitrogen) are seen to be the same shape with a mean difference of 1.68 Gy with good correlation between the two curves. The proton dose is seen to be $\sim 12\%$ higher in the asymptotic tail

Fig. 3 Nuclear dose versus cell edge to edge separation for spherical cells of radius $r_c = 4.0 \mu\text{m}$ with nuclei of $r_n = 3.0 \mu\text{m}$ and eccentricity of $\varepsilon = 0$ for boron concentrations of 10 ppm in the interstitium, 50 ppm in the cytoplasm, and 50 ppm in the nuclei. The dose includes contributions from the boron (n, α) and nitrogen (n,p) reactions for the upper curve and only from the boron (n, α) reaction for the lower curve.

($\geq 10 \mu\text{m}$ separation) than the dose from the $^{10}\text{B}(\text{n},\alpha)^7\text{Li}$ reaction alone. Since, in the current models, the nitrogen distribution is homogeneous, the $^{14}\text{N}(\text{n,p})^{14}\text{C}$ reaction will produce a constant additive dose of $\sim 2 \text{ Gy}$. Other authors in the field of BNCT microdosimetry either omit the dose from the $^{14}\text{N}(\text{n,p})^{14}\text{C}$ reaction or model it as a homogeneous distribution. In order to understand spatial variability, the dose from the $^{14}\text{N}(\text{n,p})^{14}\text{C}$ reaction will generally be omitted unless otherwise stated.

Gamma ray dose from the $^{10}\text{B}(\text{n},\alpha \gamma)^7\text{Li}$ reaction

In 93.7% of the ^{10}B interactions, a γ -ray is produced as is shown above in the equations defining the $^{10}\text{B}(\text{n,p})^7\text{Li}$ reactions. This is a 480 keV γ -ray that deposits energy along its track in the tissue with much of the energy being deposited outside of the body. An accepted ^{10}B concentration in the cytoplasm and the nuclei is $\sim 50 \text{ ppm}$ while the interstitial concentration is $\sim 10 \text{ ppm}$ (Coderre et al., 1998; Coderre and Morris, 1999; Elowitz et al., 1998). The interstitium occupies $\sim 15\%$ of the volume for the brain with cells and cytoplasm occupying the remaining volume (Haug, 1987; Moran et al., 1992) so that the number density (N) may be determined starting with the relative tissue composition:

$$N = 0.85(50 \text{ ppm}) + 0.15(10 \text{ ppm}) = 44 \text{ ppm} = 44 \frac{\text{mg}}{\text{kg}}$$

or

$$\begin{aligned} N &= \frac{44 \text{ mg } ^{10}\text{B}}{1 \text{ kg}} \left(\frac{1 \text{ g}}{1000 \text{ mg}} \right) \left(\frac{1 \text{ mole}}{10.0129 \text{ g } ^{10}\text{B}} \right) \left(\frac{6.0221367 \times 10^{23} \text{ atoms}}{1 \text{ mole}} \right) \\ &= 2.65 \times 10^{21} \frac{\text{atoms}}{\text{kg}}. \end{aligned}$$

The γ -ray energy from the ^{11}B metastable nuclear decay is:

$$E_\gamma = 0.48 \text{ MeV/interactions} = 7.69 \times 10^{-14} \text{ J/interactions}.$$

The total number of interactions, I, is given by:

$$I = N\phi\sigma$$

where the fluence, ϕ , for BNCT is a typically (Binns et al., 2005; Fukuda et al., 2003):

$$\phi = 4 \times 10^{12} \frac{\text{neutrons}}{\text{cm}^2}$$

so that the total number of interactions is:

$$I = 2.65 \times 10^{21} \frac{\text{atoms}}{\text{kg}} \left(4 \times 10^{12} \frac{\text{neutrons}}{\text{cm}^2} \right) (3837 \times 10^{-24} \text{cm}^2) = 4.093 \times 10^{13} \frac{\text{interactions}}{\text{kg}}.$$

Now consider an infinite medium, so that all of the γ -ray energy will be deposited in the medium. Then the total dose per kilogram will be given by

$$D_\gamma = E_\gamma I = 2.89 \frac{\text{J}}{\text{kg}} = 3.15 \text{ Gy}.$$

The mass energy-absorption coefficient for a 0.48 MeV γ -ray in human brain tissue may be determined from the Tables of X-Ray Mass Attenuation Coefficients and Mass Energy-Absorption Coefficients at the National Institute of Standards and Technology (NIST) online site [<https://www.nist.gov/pml/x-ray-mass-attenuation-coefficients>] and it is:

$$\mu_{en}/\rho = 3.276 \times 10^{-2} \frac{\text{cm}^2}{\text{g}}.$$

This may be applied to human brain tissue that is largely water and has a density, ρ :

$$\rho = 0.99 \frac{\text{g}}{\text{cm}^3}.$$

By combining these, the energy-absorption coefficient, μ_{en} , is:

$$\mu_{en} = 0.032 \text{ cm}^{-1}.$$

The mean chord length in a convex volume is approximately the mean distance likely to be traversed by the γ -ray as it passes through the cell. The Cauchy relation for the mean chord length in a convex volume provides such an approximation (Mazzolo, 2007; Mazzolo et al., 2003):

$$l = 4 * \frac{V}{A}$$

where V is the volume of the object and A is the area. So for a sphere of radius r , the mean chord length is given by the Cauchy Theorem:

$$l = \frac{4r}{3}.$$

In the present case of microdosimetry, the region of interest is often modeled by small cubes with sides of approximately 150 μm , which corresponds to a volume of $3.375 \times 10^6 \mu\text{m}^3 = 3.375 \times 10^{-6} \text{ cm}^3$. The cube can be approximated by a sphere of the same volume which would then have a radius, $r = 9.3 \times 10^{-3} \text{ cm}$. The mean chord length is then:

$$l = \frac{4 * 9.3 \times 10^{-3} \text{ cm}}{3} = 0.0124 \text{ cm}.$$

The dose to the sphere (with a radius of $9.3 \times 10^{-3} \text{ cm}$) may then be approximated by:

$$D = D_\gamma \left(1 - e^{-\left(\mu_{en} l / 2 \right)} \right) = 6.24 \times 10^{-4} \text{ Gy}.$$

Extrapolation to the whole brain is difficult because less is known about the distribution of boron for the entire brain. A typical glioblastoma may easily be 2–4 cm in diameter (some may be larger but would not likely be a candidate for clinical trials because killing so much tissue would result in a fatal cerebral edema). Consider a 4 cm diameter tumor that would have a volume of 33.51 cm^3 with a boron concentration of 44 ppm from above. The remainder of a typical 1400 cc brain (Lyden et al., 1994) would have a concentration of ~ 10 ppm. Let us first consider an infinite medium of uniform distribution with the number density of B defined by:

$$N = 44 \text{ ppm} \left(\frac{33.51}{1400} \right) + 10 \text{ ppm} \left(\frac{1400 - 33.51}{1400} \right) = 10.81 \text{ ppm} = 10.81 \frac{\text{mg}}{\text{kg}}.$$

So for an infinite medium:

$$I = N\phi\sigma = 9.24 \times 10^{12} \frac{\text{interactions}}{\text{kg}}$$

as before, the total γ ray dose is:

$$D_\gamma = E_\gamma I = 0.768 \frac{\text{J}}{\text{kg}} = 0.768 \text{ Gy}.$$

Approximating the brain by a sphere of volume $V = 1400$ cc, then the radius would be $r = 6.94$ cm with that mean chord length of:

$$l = 9.253 \text{ cm}$$

giving a tumor dose of:

$$D = D_\gamma \left(1 - e^{-\left(\frac{\mu_{en} l}{2}\right)} \right) = 0.106 \text{ Gy.}$$

Detailed analyses demonstrated that (Coderre and Morris, 1999) the microdosimetric or macrodosimetric (over the region of the tumor or brain) doses from the γ -ray from the $^{10}\text{B}(n, \alpha \gamma)^7\text{Li}$ reaction adds a small dose as compared to other doses that are on the order of 10–15 Gy in the microdosimetric region (at the cellular level) and can be ignored.

Dose from recoil protons

Noted above, the epithermal neutron beam is adjusted so that they are thermalized at the depth of the tumor which is usually a few centimeters into the brain for glioblastoma multiforme (GBM). Protons are bound as hydrogen atoms in organic molecules, most commonly to carbon or oxygen. Bond energies may be found in standard chemistry texts and have values of:

$$E_{H-C} = 413 \frac{\text{J}}{\text{mole}} = 4.28 \text{ eV}$$

and

$$E_{H-O} = 498 \frac{\text{J}}{\text{mole}} = 5.16 \text{ eV.}$$

Epithermal neutrons undergo scattering reactions with the protons. This elastic scattering has a rather flat cross section of ~ 20 b versus incident neutron energy over the energy range for epithermal to thermal neutrons as can be seen in plots in the ENDF data set at the National Nuclear Data Center [<https://www.nndc.bnl.gov/exfor/endf00.jsp>].

As shown above, for low energy elastic scattering reactions for energies $0 \leq E_p \leq E_n$, the average energy of the free recoil proton is $\sim$ half that of the incident neutron. The binding energy of the hydrogen to its parent organic molecule decreases the recoil proton kinetic energy in the following manner:

$$E'_p = E_p - E_B = \frac{1}{2}E_n = E_B$$

where E'_p is the net recoil proton energy and E_B is the binding energy that is equal to either E_{H-C} or E_{H-O} that defines a minimum average energy that the neutron must possess in order to break the bond and leave the proton with energy $E'_p \geq 0$ so that the neutron must possess an energy:

$$E_n \geq 2E_B$$

in order to break a free proton from the molecule. Thus, the neutrons must have an energy greater than ~ 10 eV to generate recoil protons. Neutrons with energies on the order of 0.025 eV will not have sufficient kinetic energy to break the common hydrogen bonds.

Neutrons that have not yet been thermalized can potentially break the chemical bonds as long as $E_n \geq 2E_B$. So, for the H-C bond, the neutron will have more than 8.56 eV of kinetic energy while the energy required to break a H-O bond with elastic scattering would have to be greater than 10.32 eV. If the neutron kinetic energy is equal to the bond energy, the bond will be broken but the proton will have no kinetic energy to dissipate and so provides no dose. Also, low energy neutrons, (a few eV or less), may excite molecular vibrational modes so that not every interaction of sufficient energy to break a bond will produce a recoil proton. The exceedingly large number of different molecular species found in humans with complex vibrational excitation patterns makes the estimation of this mode of energy dissipation beyond the scope of this work. Since this is looking at a depth in the tissue where nearly all neutrons are thermalized, there is no contribution to the microdosimetry from recoil protons because none are produced by thermal neutrons.

Dose from the $^1\text{H}(n, \gamma)^2\text{H}$ reaction

The cross section for thermal neutron capture by hydrogen is not small and hydrogen is found in abundance in all organic molecules. The thermal neutrons will be captured by the hydrogen nucleus which will emit a 2.22 MeV γ -ray in the following reaction:

The cross section for thermal neutron capture by a hydrogen nucleus may be found online at the National Nuclear Data Center and is:

$$\sigma = 0.332 \text{ b.}$$

where the γ -ray energy from the capture of the neutron by the proton is:

$$E_\gamma = 2.2 \text{ MeV/interactions} = 3.56 \times 10^{-13} \text{ J/interactions.}$$

The concentration of ^1H in human tissue is $\sim 10\%$ by weight so using the same calculations as above the number density is:

$$N = 5.97 \times 10^{25} \text{ H} \frac{\text{atoms}}{\text{kg tissue}}.$$

The total number of interactions is:

$$I = 7.93 \times 10^{13} \frac{\text{interactions}}{\text{kg}}.$$

As before, consider an infinite medium so that all of the γ -ray energy will be deposited in the medium then the γ -ray dose is:

$$D_\gamma = 28.22 \frac{\text{J}}{\text{kg}} = 28.22 \text{ Gy}$$

The mass energy-absorption coefficient for a 2.0 MeV γ -ray in human brain tissue may be determined from the Tables of X-Ray Mass Attenuation Coefficients and Mass Energy-Absorption Coefficients at the (NIST) online site:

$$\frac{\mu_{en}}{\rho} = 2.595 \times 10^{-2} \frac{\text{cm}^2}{\text{g}}$$

where the density for human brain tissue as above results in

$$\mu_{en} = 0.026 \text{ cm}^{-1}.$$

As before, for a typical human brain volume of 1400 cc the brain can be approximated by a sphere of volume of radius $r = 6.94 \text{ cm.}$ so that the mean chord length is:

$$l = 9.25 \text{ cm.}$$

The dose to the whole brain is then

$$D = D_\gamma \left(1 - e^{-\left(\frac{\mu_{en} l}{2}\right)} \right) = 0.11 D_\gamma = 3.16 \text{ Gy}$$

The volume over which a 2.2 MeV photon will deposit its energy is significantly larger than the brain volume. In microdosimetry, the region of interest is much smaller—approximately cubes of side $\sim 150 \mu\text{m}$ corresponding to a volume of $3.375 \times 10^6 \mu\text{m}^3$ which could be approximated by a sphere of the same volume with a radius of $r = 9.3 \times 10^{-3} \text{ cm.}$ Then mean chord length becomes

$$l = 0.0124 \text{ cm}$$

Which energy deposition by the 2.2 MeV photon in this volume will result in a dose to the region of interest of:

$$D = 4.94 \times 10^{-3} \text{ Gy.}$$

Macrodosimetric treatment doses to the normal brain dose are typically 2–3 Gy with a tumor dose of 30–61 Gy (Joensuu et al., 2003). The dose from the $^1\text{H}(n,\gamma)^2\text{H}$ reaction adds a negligible component to the total dose and will not be further considered. Likewise, the dose from the radiative capture will not be considered in this treatment.

Summary of the components to the radiation milieu

Several authors have reported that the $^{10}\text{B}(n,\alpha\gamma)^7\text{Li}$ reactions account for approximately 86% of the total dose to tumor cells (Barth et al., 2005; Sweet, 1997). Values listed in Table 4 were calculated for cells of radius $5.0 \mu\text{m}$, nuclear radius $4.0 \mu\text{m}$, eccentricity of $\epsilon = 0$, and a cell edge to cell edge separation of $0.0 \mu\text{m}$. The dose from recoil protons is dependent upon the details of the epithermal neutron beam that has flat neutron energy distribution in the energy range of interest. Elastic cross sections as a function of incident neutron energy are also flat in the epithermal energy range so that the elastic proton doses can be averaged as an approximation of the actual dose. These results are presented in Table 4 where there is good agreement with experimental determinations, especially since there are no contributions from neutron beam contaminants in these calculations. The table shows that the $^{10}\text{B}(n,p)^7\text{Li}$ and $^{14}\text{N}(n,p)^{14}\text{C}$ reactions account for over 97% of the dose. This is a crucial point for BNCT as a very large dose is delivered to a tumor with much smaller doses to surrounding normal tissue by assuming a preferential uptake of a ^{10}B containing carrier molecule by the tumor.

Table 4 Dose contribution from different radiation components.

Radiation component	Dose (Gy)	Percent of total (%)
$^{10}\text{B}(n,\alpha)^7\text{Li}$	43.12	89.8
$^{14}\text{N}(n,p)^{14}\text{C}$	3.79	7.9
γ from $^{10}\text{B}(n,\alpha)^7\text{Li}$	0.099	0.21
$^1\text{H}(n,\gamma)^2\text{H}$	0.0049	0.01
Elastic recoil protons	1.02	2.12
Totals	48.04	100.0

**Fig. 4** The dose for the three regions of interest for typical cell sizes of radius $r_c = 5.0 \mu\text{m}$ with spherical concentric nuclei of radius $r_n = 4.0 \mu\text{m}$ and boron concentrations that have been experimentally determined as 50 ppm in the cells and 10 ppm in the interstitium.

How the boron distribution affects the dose

As the boron concentration increases in a region, the number of neutron-boron interactions will increase proportionately. Since the dose is localized, the result scales linearly. Fig. 4 shows a typical case for spherical cells of radius $r_c = 5.0 \mu\text{m}$ with spherical concentric nuclei of radius $r_n = 4.0 \mu\text{m}$ where the dose is seen to be higher when the cells are near to one another as shown. In the asymptotic region where the cells are too far apart to affect each other, the nuclei and cytoplasm receive a larger dose than does the interstitium, where the concentration is one-fifth that of the cells. In order to better understand the role of the boron concentration, the dose may be broken into components. The components may be calculated by setting the boron concentration to zero in two of the three regions with the remaining region having the concentration as depicted in Fig. 5. By examining the nuclear dose only, it is seen that the sum of the three component curves produces the independently calculated upper curve that demonstrates the linearity of the dose in a given region as a function of the boron concentration. Of note is the small increase noted in the first portion of the nuclear dose when all of the boron is in the interstitium. The increase is due to the empty (of boron) cells being next to each other being replaced by boron containing interstitial space as the cells separate. A similar effect is seen in Fig. 6 where only the dose to the interstitium is shown. The three lower curves are once again seen to sum to the independently calculated upper curve. The interstitial dose (when all the boron is concentrated in the interstitial space) is of interest since it is seen to increase with separation. This is because when the cells are close together a larger proportion of the ions will deposit energy into a cell than into the interstitium. As the cells separate, a larger proportion of the ions will have their entire track in the interstitium because a greater portion of the track will be confined to the much larger interstitium.

Also of interest are cases where the ratio of cellular boron to interstitial fluid and to normal cells are higher than has been currently seen with boronophenylalanine (BPA), which is the most commonly used boron-10 carrier molecule. Early animal experiments have produced ratios of 10–20:1 which would mean 100–200 ppm in the cells with 10 ppm in the interstitial fluid and normal cells (Kabalka et al., 2004). The effect of these ratios is seen in Fig. 7 where the corresponding nuclear and interstitial curves

Fig. 5 The nuclear dose only for typical cell sizes of radius $r_c = 5.0 \mu\text{m}$ with spherical concentric nuclei of radius $r_n = 4.0 \mu\text{m}$ and boron concentrations that have been experimentally determined. The three lower curves are the produced by allowing only one of the three regions of interest to have boron with the remaining two regions to have a boron concentration of zero. The sum of the lower three curves is seen to produce the independently calculated upper curve.

Fig. 6 The interstitial dose only for typical cell sizes of radius $r_c = 5.0 \mu\text{m}$ with spherical concentric nuclei of radius $r_n = 4.0 \mu\text{m}$ and boron concentrations that have been experimentally determined. The sum of the lower three curves is seen to produce the independently calculated upper curve.

are seen to be twice the dose at 200 ppm in the cells compared to 100 ppm. The cellular doses are seen to be enormous and the scaling is again seen to be linear. These potentially obtainable doses are truly remarkable when it is remembered that the lethal free air *whole body dose* required for a 95% lethality is ~ 7 Gy. The most important aspect of Fig. 7 is that the nuclear dose is > 50 Gy even for widely separated cells for the 200:1 cell to interstitium boron concentrations. So that active (in the sense of avidly

Fig. 7 The dose for the three regions of interest for typical cell sizes of radius $r_c = 5.0 \mu\text{m}$ with spherical concentric nuclei of radius $r_n = 4.0 \mu\text{m}$ and boron concentrations that are potentially achievable with new boron carrier molecules of 200 ppm in the cells and 100 ppm in the cells with 10 ppm in the interstitium in both cases.

accumulating the boron carrier molecule) tumor cells will be destroyed with doses as high as 65 Gy for nuclei in the body of the tumor. At the same time, the surrounding *tissue* will receive < 5 Gy, which is well below a dose that will kill brain cells. The normal tissue will be preserved with much more effective killing of tumor cells even if widely separated. Thus, as new boron carrier molecules are produced that increase the tumor to normal tissue ratio, the effectiveness of the modality will likewise increase.

The effects of cell geometry on the dose

The hypothesis of this dissertation is that cells closely packed together will provide a significant dose to neighboring cells as well as to the interstitial space which in the present model contains normal cells and cells in the G_0 (resting) phase. The model permits dose variance estimations to both the cells and the interstitium as the cells are separated. Observing the separation of the tumor cells corresponds to examining the edge of tumors. The cells will gradually thin out until they are more widely separated. This situation is especially true for infiltrative tumors such as GBM but less so for other tumors such as melanoma which tends to be more circumscribed with few cells separated from the main tumor body. In order to understand the actual *in vivo* microdosimetry, boron concentrations will be set as 10 ppm in the interstitium, 50 ppm in the cytoplasm, and 50 ppm in the nuclei, which is similar to the determinations of boron concentrations in actual patients as determined by Coderre et al. (1998) and Olsson et al. (1998), unless otherwise specified. The size and shape of normal cells is quite variable with cells varying from small (on the order of 3–4 μm in radius) to those up to radii of over 10 μm . Likewise, nuclei can vary from a radius of 1–2 μm up to 8–10 μm for some types of tumor cells. Cell shapes are also quite variable. Some are small, almost cuboidal, as in the Kupffer cells in the liver, others are spherical (especially in white blood cells such as lymphocytes and monocytes), and some are elongated such as myocytes (muscle cells) and neurons (diFiore, 1981; Junqueira and Carneiro, 1980; Reith and Ross, 1977). Spinal neurons may be more than a meter in length extending from the cell body in the upper lumbar spine to the foot. Tumor cells typically display more variability in size and shape than the tissues from which they arise especially in regard to the nuclei which are often larger and more eccentric in shapes (Curran, 1972; Escourolle and Poirier, 1978; Robbins and Cotran, 1979). Furthermore, new studies are demonstrating that living cells are constantly changing shape responding to the local biochemical and physical milieu. The programs used in this modelling were designed for ellipsoidal tumor cells. Changing the underlying geometry allows the modelling of the microdosimetry of different tumors. For example, closely packed spherical cells simulate melanoma whereas a very eccentric geometry with spherical nuclei far from the cell center better approximates neurons. Glioblastoma multiforme cells are somewhere in between these two geometries. To better understand the microdosimetry of BNCT, several cases will be considered.

Fig. 4 shows the effect of separating cells that initially are just touching and gradually increasing the edge-to-edge separation. The figure shows a 16% increase in the nuclear dose from the asymptotic 'tail' to the peak when the cells are just touching. This means that the nucleus of each cell receives an additional dose from neighboring cells which could be viewed as a near neighbor effect. Also, significant is the ratio of 2.46 of the maximum interstitial dose when the cells are just touching to the dose in the asymptotic tail of the interstitial dose. Thus, the interstitium receives a larger dose when neighboring cells are closer together, i.e., the dose from

^{10}B nuclei in the cells is more concentrated when the cells are closer to one another. As the cell radius increases, the effect on the nuclei diminishes if the nuclear radius does not increase in a like manner. This decrease in effect can be seen in Fig. 8 for spherical cells of radius $8.0\text{ }\mu\text{m}$ and a nuclear radius of $4.0\text{ }\mu\text{m}$. The dose to the nuclei is essentially flat whereas the dose to the interstitium shows the earlier noted effect. The explanation has to do with the short range of the ions. The maximum range of the alpha particle from the $^{10}\text{B}(\text{n},\alpha)^7\text{Li}$ and $^{10}\text{B}(\text{n},\alpha\gamma)^7\text{Li}$ reactions (refer to Table 3) is $9.06\text{ }\mu\text{m}$ (6.3% of the time) and $7.39\text{ }\mu\text{m}$ (93.7% of the time) for a mean range of $\sim 7.5\text{ }\mu\text{m}$. Similarly, the mean range of the lithium nucleus is $\sim 4\text{ }\mu\text{m}$. When the cell radius is $8.0\text{ }\mu\text{m}$ and the nuclear radius is $4.0\text{ }\mu\text{m}$, a boron disintegration must be near to the cell edge along a line of centers for the ions to reach the nearest neighbor nucleus. When the cell edges are $1\text{ }\mu\text{m}$ apart, essentially no lithium ions reach the nearest neighbor nucleus and when the edges are $5\text{ }\mu\text{m}$ apart there is no contribution from the alpha particles. Fig. 8 contains a summary of the dose as a function of separation for cells when the cell radius is $8.0\text{ }\mu\text{m}$ and the nuclear radius is $4.0\text{ }\mu\text{m}$. The decrease in the nuclear dose is small decrease in the first $2\text{--}3\text{ }\mu\text{m}$. Thus, the geometry of the cells has an impact upon the nuclear doses. The interstitial dose is affected in a similar manner, with the magnitude of the effect (peak dose/asymptotic dose) is lower than that presented in Fig. 4. The ratio of peak dose/asymptotic dose for the smaller cells (Fig. 4) is ~ 2.3 versus the larger cells where it is ~ 1.9 (Fig. 8). This effect can be understood by first examining the packing fraction of a region defined for this case as the total volume inside the cells (ellipsoids) divided by the total volume of the region of interest. So consider a cube that encloses eight spheres of radius r so that the cube has side $l = 2 \cdot (2r) = 4r$ and the volume of the cube is:

$$V_C = l^3 = (4r)^3 = 64r^3.$$

The total volume enclosed by the spheres is eight times the volume of one of the spheres or:

$$V_s = 8 \left(\frac{4}{3} \pi r^3 \right)$$

The packing fraction, P_f , is then given by:

$$P_f = \frac{V_s}{V_c} = \frac{8 \left(\frac{4}{3} \pi r^3 \right)}{64r^3} = \frac{\pi}{6} = 0.524$$

which is a constant so that the variation seen is not due to the packing fraction for a given separation. Now consider the surface to volume ratio of a sphere that is:

$$R_{SV} = \frac{(4\pi r^2)}{\left(\frac{4}{3} \pi r^3 \right)} = \frac{3}{r}.$$

Fig. 8 Dose as a function of cell edge to edge separation for large spherical cells of radius $r_c = 8\text{ }\mu\text{m}$ with nuclei of $r_n = 4\text{ }\mu\text{m}$ for boron concentration of 10 ppm in the interstitium, 50 ppm in the cytoplasm, and 50 ppm in the nuclei demonstrating the increase in dose to neighboring cells and interstitium (at small separations). The effect is less than that observed with smaller cells.

Fig. 9 contains a summary of the average dose to the interstitium over 50 cases at 4 cell radii (5, 8, 11, and 14 μm) for a separation of 0.0 μm fit by non-linear regression to:

$$D = D_0 + \frac{a_0}{r}.$$

The fit is seen to be rather good, meaning that part of the explanation for the smaller dose has to do with the fact that the surface area is increasing less rapidly than the boron containing cell volume. However, the fit does not exactly fit $\frac{3}{r}$, which suggests that there are other factors that must be considered such as ions that pass from one cell to another. The basic observations are that near neighbors contribute to the dose of a cell and that, when cells are widely separated, the dose to the interstitium decreases. These findings have significant implications for the types of tumors that can be treated with BNCT.

The effects of the cell radius and cell separation are shown in Fig. 10 for the interstitial dose. The dose in the interstitium is highest when the cells are small and densely packed. As the cells increase in radius or the cells are farther apart, the dose decreases and, if both occur, the dose can decrease by a factor of 2. Thus, normal tissue will receive lower doses when the tumor cells are far apart and large. The corresponding nuclear dose for the same geometries is shown in Fig. 11. The data in this figure reveal that the nuclear dose decreases as the cells become more separated but increases as the cells increase in size. For large cells, there is little change as the cells separate for the concentric nuclei. Thus, large tumor cells display less near neighbor effects because of the distance to the nucleus. Since the idea of BNCT is to deliver a significantly larger dose to the tumor than is delivered to normal tissue, it is useful to plot the ratio of the total cellular dose to the interstitial dose, which represents normal tissue, as a function of separation and cell radius. The results are plotted in Fig. 12 where it is clear that normal cells far from the tumor will have a greater therapeutic benefit than those near or in the tumor. This once again demonstrates the effects of neighboring cells on the dose. In Fig. 13, the relative dose to the nucleus, as compared to the cytoplasm is plotted as a function of the cell radius for cellular boron concentrations of 50 ppm and 200 ppm while the interstitial boron concentration is 10 ppm for each case. The slight proportional decrease in dose to the nuclei is geometric for the increasing cytoplasmic volume in which an ion can travel without encountering the nucleus. As the nuclear volume goes from 51.2% of the cell volume for a nuclear radius of 4.0 μm and a cell radius of 5.0 μm to 4.8% when the cell radius increases to 11 μm , any given ion is more likely to deposit all of its' energy in the cytoplasm rather than in the nucleus.

The implications of these results combined with an improved boron carrier are obvious. Consider cells of radius 10 μm with concentric nuclei of radius 4 μm separated from one another by 20 μm and boron concentrations of 200 ppm in the cell and 10 ppm in the interstitium. In this situation, the boron reaction dose would be 5.82 Gy to the interstitium, 62.71 Gy to the cytoplasm, and 82.28 Gy to the nuclei. The interstitial dose is still reasonable while the nuclear dose is quite high with a nuclear to interstitial dose ratio > 15 . This would kill all cells that concentrated the boron carrier molecule with little damage to normal tissue in a single treatment. The patient could receive subsequent treatments to hopefully destroy any tumor cells far from the main tumor that were in a G_0 or resting state. The combination of boron distribution and tumor cell architecture has an enormous impact upon the dose to the tumor cells.

The eccentricity of an ellipsoid is a measure of how far the ellipsoid is from spherical. The volume, defined by a sphere of radius r , remains constant as the eccentricity varies. This definition of an ellipsoid also possesses rotational symmetry about

Fig. 9 Interstitial dose averaged over 50 cases with no separation at four cell radii. Fitting is performed non-linearly with the function $D = D_0 + a_0/r$ as derived from the ratio of the surface/volume for spheres. Nonlinear regression was used to fit the data with $D_0 = 5.97$ Gy and $a_0 = 24.52$ Gy $\cdot \mu\text{m}$.

Fig. 10 The dose to the interstitium as a function of cell radius for a concentric nucleus of radius 3.0 μm and cell edge to edge separation for boron concentrations of 50 ppm in the cell (nucleus and cytoplasm) and 10 ppm in the interstitium.

the z axis. When ϵ equals zero, the ellipsoid is a sphere. As ϵ gets larger, the ellipsoid becomes more elongated or prolate, which is referred to as prolate as shown in Fig. 14. Eccentricities in the range $-1 < \epsilon < 0$ lead to a flattened (pancake) shape referred to as oblate. Another view of the ellipsoidal cells is seen in the two cross sections of an ellipsoidal cell shown in Fig. 15 with a radius of 10 μm and eccentricity of 2.5 encompassing a nucleus of radius 4 μm . To determine the effect of the eccentricity on dose, the ratio of the nuclear dose for an ellipsoid with a radius of 10 μm to the dose of an equal-volume sphere both with concentric nuclei is shown as a function of eccentricity and cell separation in Fig. 16. The plot is essentially flat indicating that the response is like that just described for large spherical cells. Ellipsoidal cells can be approximated by spherical cells especially for understanding effects rather than numerical values.

Finally, the nucleus can be allowed to be eccentrically centered. It can be randomly eccentrically centered in every cell, randomly eccentric in the first cell that is then applied to all subsequent cells, or a fixed direction or a fixed distance from the center specified with the other parameter randomly determined. The results from this are of interest because there is essentially no difference between the spherically concentric or randomly placed nuclei. The results are surprisingly similar. For example, the sum of the squares difference between spherical cells of radius 10 μm with concentric spherical nuclei of radius 4 μm and spherical cells of radius 10 μm with randomly placed spherical nuclei of radius 4 μm is 0.06. The data are very similar to those for concentric spherical nuclei and spherical cells and the same observations hold true.

Salient points

Boron distribution, cell geometry, and the relationship between cells are important factors in determining the total nuclear dose. The dose to the nucleus is the crucial dose that results in a loss of homeostasis. DNA damage can also lead to the inability for successful mitosis that also leads to cellular death or a halt to further replication (either case is successful cancer control). Lastly, damage to the DNA can lead to advanced apoptosis, i.e. the programmed cell death that is part of all cells is temporally advanced. Thus, the results are viewed primarily from the standpoint of the nuclear dose.

The interpretation of the results must take into account the interstitium which is the fluid filled space between cells in a tissue. The interstitium refers to the space between tumor cells or more specifically between cells loaded with boron. In this model, the interstitium could contain normal cells or tumor cells that do not avidly uptake the boron carrier. The dose to the interstitium in tumors such as malignant melanoma and adenocarcinoma of the colon represents the dose to the normal tissue so that low doses

Fig. 11 The nuclear dose as a function of cell radius for a concentric nucleus of radius $3.0\ \mu\text{m}$ and cell edge to edge separation for boron concentrations of 50 ppm in the cell (nucleus and cytoplasm) and 10 ppm in the interstitium.

are important. In infiltrative tumors such as glioblastoma multiforme and angiosarcoma, the interstitium will contain both normal cells and tumor cells that did not avidly uptake the boron agent. This has significant clinical significance as will be discussed.

As noted above for Fig. 4, the dose to the interstitium is ~ 2.4 greater when the cells are touching than when widely separated. Thus, closely packing cells increases the nuclear dose that improves efficacy. The greater increase in dose to the interstitium can be interpreted to mean that cells without boron loading will receive a significantly larger dose when cells are close together but a small dose when they are apart. Furthermore, the ratio of the nuclear dose to interstitial dose ratio is greater when the cells are widely separated, with the tumor cells still receiving a dose greater than 15.5 Gy. Cell death is a statistical phenomenon and is expressed by a cell survival curve as illustrated in Fig. 17. The doses delivered by BNCT are adequate for cell killing especially when the dose to the cytoplasm is combined with the nuclear dose to determine the cellular dose. For example, referring again to Fig. 4, the cellular dose for no separation is ~ 32 Gy and for the asymptotic range is ~ 27 Gy. Both doses are clearly lethal.

The distribution of boron in the cell is also seen to be important with the greatest dose occurring when the boron is concentrated in the nuclei rather than the interstitium by a factor of ~ 2 as seen in Fig. 5. The boron in the interstitium provides a small nuclear dose and is the most important constituent of the dose to the interstitium itself. The greater the concentration of boron in the cell holding the interstitial boron concentration constant, the greater the nuclear dose, in a basically linear nature while the effect on the interstitial dose is minimal. This highlights the dependence of BNCT upon boron carrier molecules. If a carrier molecule can increase the absolute tumor cell boron concentration and increase the ratio of cell to interstitium boron, the efficacy of BNCT will greatly increase.

As cells increase in radius while keeping a constant nuclear radius, the nuclear dose will increase and the influence of nearby cells decreases. Also, the greatest ratio of cell to interstitial dose occurs for large separated cells. The influence of a non-concentric nucleus is relatively small for the geometries studied.

Summary

In summary, the nuclear dose for small cells is increased by nearby cells but shows little near neighbor effect for large or greatly separated cells. The greater the boron concentration, the greater the nuclear dose. If the cell to interstitial boron concentration

Ratio of cell dose to interstitial dose

Fig. 12 The ratio of the dose to the cell to the dose to the interstitium as a function of cell radius and cell separation for boron concentrations of 50 ppm in the cell (nucleus and cytoplasm) and 10 ppm in the interstitium.

Nuclear to cytoplasmic dose ratio
as a function of cell radius

Fig. 13 The relationship of the nuclear to cytoplasmic dose ratio for two different cellular boron concentrations and for varying cell radii. The noisiness in the 50 ppm boron concentration data is due to the smaller number of boron reactions in total as well as the smaller proportion of the total number of reactions for the region of interest, i.e. 20:1 versus 5:1.

Fig. 14 A representative ellipsoid with radius $10\ \mu\text{m}$ and an eccentricity of 1.5.

Fig. 15 Two cross sections through a cell with eccentricity of 2.5 and radius of $10\ \mu\text{m}$ and concentric spherical nucleus of radius $4\ \mu\text{m}$.

increases as the cellular boron increases, the interstitial dose changes little, but if the cellular concentration of boron is linearly increased, this should translate into much greater efficacy.

BNCT has been used to treat several malignancies including glioblastoma multiforme, malignant melanoma, head and neck tumors, undifferentiated thyroid carcinoma, and metastatic adenocarcinoma of the colon (Aihara et al., 2006; Ariyoshi et al., 2007; Behr et al., 1999; Dagrosa et al., 2007, 2002, 2003; Joensuu and Tenhunen, 1999; Kankaanranta et al., 2007; Kato et al., 2004; Kennedy et al., 2004; Kouri et al., 2004; Morris et al., 2005; Nano et al., 2004; Pettersson et al., 1992; Pisarev et al., 2007, 2006; Posner et al., 1993; Seppala et al., 2004; Viaggi et al., 2004). Of these, the most clinically studied tumor is GBM. The standard therapy for glioblastoma multiforme is neuro-surgical resection followed by 36 standard external photon beam radiation treatments and in some cases chemotherapy. This standard protocol provides a life expectancy of approximately 12 months from the time of diagnosis (Wilson et al., 1991). The BNCT trials substitute BNCT for conventional photon therapy and demonstrate a survivability of approximately 14 months (Busse et al., 2003, 1997; Diaz et al., 2000; Iwakura et al., 2002; Mishima, 1994). The clinical trials observed that the glioblastoma recurs at the edge of the tumor bed. Since the tumor is infiltrative, the edge of the tumor will be ragged with cells extending into the surrounding tissue. The microdosimetry of BNCT provides an answer. Consider cells in this periphery that did not accumulate a significant boron concentration (in G_0 phase or poor local availability of the boron carrier—usually BPA). This would correspond to a cell in the interstitium that is in the widely separated region. These cells will receive only a few Gray of dose ($\sim 5\ \text{Gy}$) unlike a cell in the interstitium in the tightly packed case with the dose being more than twice that of the periphery. These doses can go from possible to likely lethality. This model would indicate that infiltrative tumors cannot be successfully treated with BNCT with current boron carrier molecules. The only way that an infiltrative tumor can be successfully treated with BNCT is to find an agent that concentrates in all tumor cells avidly, even if the cell is in the G_0 phase, or to administer therapy over

Comparison of the dose to an ellipsoidal cell
and an equivolume spherical cell

Fig. 16 A comparison of the dose to an ellipsoidal cell and an equivolume sphere both with concentric nuclei of radius $4.0\ \mu\text{m}$. The spherical cell and ellipsoidal cell have the same radius of $10\ \mu\text{m}$. For an eccentricity of ϵ , the three axes (a , b , and c) of the ellipsoid are defined as $c = r(1 + \epsilon)$ and $a = b = \frac{r}{\sqrt{1+\epsilon}}$.

Fig. 17 Illustrative cell survival curves showing the linear quadratic nature of cell demise in radiation with different values of α and β taken from the literature.

several days. Though giving dose fractions might be successful, fractionating the treatment decreases the attractiveness of the therapy when compared to a single session treatment.

The microdosimetry of BNCT is dependent upon cellular geometry and on boron concentrations in the nucleus, cytoplasm, and interstitium. Clinical results correlate with microdosimetric predictions. Future therapies with radiation will have increasing attention paid to the microdosimetry as modalities become more focused and specific.

Glossary of Terms

Absorbed dose, D The fundamental radiation dose quantity given by

$$D = \frac{d\bar{\epsilon}}{dm}$$

where $d\bar{\epsilon}$ is the average energy imparted to matter of mass dm by ionizing radiation. The SI unit of absorbed dose is joule per kilogram (J kg^{-1}), and its special name is gray (Gy). For purposes of radiation protection and assessments of health risks from exposure to ionizing radiation, the quantity of interest is the average absorbed dose in a tissue or organ (T) given by

$$D_T = \frac{\epsilon_T}{m_T}$$

where ϵ_T is the total energy imparted by ionizing radiation in tissue or organ T and m_T is the mass of that tissue or organ.

Activity, A The number of nuclear transformations (decays of radionuclides) occurring in a given quantity of material per unit time. The SI unit of activity is per second (s^{-1}), and its special name is becquerel (Bq).

Alpha decay Process of radioactive decay in which the nucleus of a heavy element undergoes spontaneous emission of an alpha particle resulting in the nucleus of the decay product with two less protons and two less neutrons. Alpha particles are emitted with discrete energies that are characteristic of the emitting nuclei. See also "alpha particle."

Alpha particle Positively charged particle of electric charge $+2$, identical to the nucleus of a helium-4 atom consisting of two protons and two neutrons, emitted spontaneously from the nucleus in decay of some radionuclides. Alpha particles have low penetrating power and short ranges in tissue and air. Health risks from exposure to alpha particles occur mainly when radionuclides are inhaled, ingested, or absorbed through the skin. Higher-energy alpha particles also can irradiate radiosensitive cells in the basal layer of the skin when alpha-emitting radionuclides are deposited on, or located close to, most areas of the body surface.

Ambient dose equivalent, $H^*(10)$ The dose equivalent at a point in a radiation field that would be produced by the corresponding expanded and aligned field in the ICRU sphere at a depth of 10 mm on the radius vector opposing the direction of the aligned field. The SI unit of ambient dose equivalent is joule per kilogram (J kg^{-1}), and its special name is sievert (Sv). See also "directional dose equivalent," "personal dose equivalent," and "operational quantity."

As low as reasonably achievable (ALARA) See "optimization of protection."

Atomic mass number, A The number of protons and neutrons in the nucleus of an atom.

Atomic number, Z The number of protons in the nucleus of an atom. It determines the chemical properties of an element as well as its place in the periodic table.

Auger electron An electron, similar to an internal conversion electron, emitted from an atom when the energy produced by the filling of a vacancy in an inner shell with an electron from an outer shell of higher energy is transferred to another electron, rather than emitted as a characteristic X ray. Auger electrons are produced in decay of many radionuclides. They also are produced when an inner-shell vacancy is created by irradiation of an atom by photons or electrons.

Becquerel (Bq) The special name for the SI unit of activity: $1 \text{ Bq} = 1 \text{ s}^{-1}$.

Beta decay A form of radioactive decay in which a neutron in the nucleus of an atom is transformed into a proton, thereby increasing the atomic number by one unit, and an electron and antineutrino are emitted from the nucleus. Kinetic energies of emitted electrons have a continuous distribution from zero energy to a maximum value called the endpoint energy. See also, "beta particle," "electron capture," and "positron decay."

Beta particle Energetic electron or positron (positively charged electron) emitted spontaneously from the nucleus in the decay of some radionuclides. Beta particles are not highly penetrating, and higher-energy beta particles have a range in tissue of no more than a few cm.

Bethe stopping power The energy loss of an ion per unit distance traveled in a material, $\frac{d\epsilon}{dX}$. It is also known as the linear energy transfer.

Binding energy The energy required to remove a subatomic particle from an atom, whether removing an electron from the orbital shell of the atom, or a proton or neutron from the nucleus of the atom.

Bragg peak The peak on a curve of the energy loss of ionizing radiation during its travel through matter. For protons, alpha particles, and other ions, the peak is quite pronounced and occurs close to the terminal point of the path of travel. This property makes beams of these particles quite useful in treating relatively small tumors in cancer patients.

Bremsstrahlung Electromagnetic radiation (X rays) produced in a continuous energy spectrum by the deceleration of charged particles, such as when charged particles are decelerated in passing through matter or decelerated, either by a change in velocity or a change in direction, in a device that produces charged particle beams.

Collective effective dose or effective dose equivalent The sum of effective doses or effective dose equivalents to individuals in a defined group from a specified source within a specified time period, or the product of the average effective dose or effective dose equivalent to individuals in a defined group within a specified time period and the number of individuals in that group. The SI unit of collective effective dose or effective dose equivalent is joule per kilogram (J kg^{-1}), and its special name is person-sievert (person-Sv).

Committed effective dose or effective dose equivalent The effective dose or effective dose equivalent received over a specified time following an intake of radionuclides by inhalation, ingestion, or absorption through the skin. The commitment period usually is taken to be 50 years for adults and to age 70 for children.

Committed equivalent dose or average dose equivalent The equivalent dose or average dose equivalent received in a particular organ or tissue over a specified time following an intake of radionuclides.

Compton effect An attenuation effect in which an incident photon interacts with (scatters from) an orbital electron in an atom to produce a recoil electron, a residual ionized atom, and a photon of energy less than the energy of the incident photon.

Contamination Unwanted radioactive material deposited in or on the surface of structures, areas, objects, or people.

Coulomb (C) The SI unit of electric charge, defined as the quantity of electricity conveyed in 1 s by a current of 1 A. One coulomb is an electric charge of $1/e$, where e is the charge of an electron equal to $1.602 \times 10^{-19} \text{C}$.

Critical organ The tissue or organ that is most susceptible of radiation damage resulting from exposure conditions of interest, taking into account doses received by different tissues or organs under those conditions. The critical organ often is the tissue or organ receiving the highest dose, especially when internal exposure is the primary concern.

Cross section, σ A measure of the probability that a specific process will occur when an incident radiation interacts with an orbital electron or electrons or with the nucleus of atoms in a target material and given in SI units of m^2 . It can be thought of conceptually as the size (area) of the object (an atom or its nucleus) that an incident photon or particle must hit for the process of interest to occur. A commonly used unit of cross section is "barn" where $1 \text{ b} = 10^{-24} \text{ cm}^2$.

Curie (Ci) The conventional unit of activity prior to introduction of SI units, defined originally as the rate of radioactive decay (number of decays per second) in 1 g of radium and later as an activity of exactly $3.7 \times 10^{10} \text{ Bq}$.

Decay constant, λ The probability that a radionuclide will decay per unit time, equal to $\ln(2)/T_{1/2}$, where $\ln$ denotes a natural logarithm and $T_{1/2}$ is the radionuclide half-life. The reciprocal of a decay constant ($1/\lambda$) is the mean (average) lifetime of a radionuclide. The decay constant relates the activity of a radionuclide, A , in a given quantity of material to the number of atoms, N , of that radionuclide in the material: $A = \lambda N$.

Decay law A mathematical expression of the amount of activity, A , of a radioactive material remaining at time t , given by $A(t) = A_0 e^{-\lambda(t-t_0)}$, where A_0 is the initial activity at time t_0 .

Decay product A radionuclide produced in decay of another radionuclide.

Deterministic effect See "tissue reaction."

Directional dose equivalent, $H'(d, \Omega)$ The dose equivalent at a point in a radiation field that would be produced by the corresponding expanded field in the ICRU sphere at a depth, d , on a radius in a specified direction, Ω . The SI unit of directional dose equivalent is joule per kilogram (J kg^{-1}), and its special name is sievert (Sv). See also "ambient dose equivalent," "personal dose equivalent," and "operational quantity."

Dose (1) A general term often used to refer to exposure of a material to ionizing radiation. (2) Term which, when quantifying exposure of a material to ionizing radiation, means "absorbed dose" but, in exposure of persons or other living things, does not denote other dosimetric quantities that account for the biological effectiveness of different radiation types, including "dose equivalent," "equivalent dose," "effective dose," "effective dose equivalent," and "radiation-weighted absorbed dose."

Dose coefficient A term used to describe the quantity of dose per unit exposure or dose per unit intake of a radioactive substance.

Dose constraint A prospective and source-related restriction on the individual dose from a source, which provides a basic level of protection for the most highly exposed individuals from a source and serves as an upper bound on the allowable dose in optimization of protection for that source (application of the ALARA principle).

Dose equivalent, H The product of the absorbed dose, D , and the quality factor, Q , for a radiation type of interest at a point in tissue:

$$H = DQ$$

The SI unit of dose equivalent is joule per kilogram (J kg^{-1}), and its special name is sievert (Sv).

For purposes of radiation protection and assessments of health risks from exposure to ionizing radiation, the quantity of interest is the average dose equivalent in a tissue or organ. The average dose equivalent has been superseded by the equivalent dose.

Dose limit Value of the effective dose, effective dose equivalent, equivalent dose, or average dose equivalent to individuals in planned exposure situations that shall not be exceeded.

Effective dose, E The tissue-weighted sum of equivalent doses in specified tissues and organs, first defined in ICRP Publication 60 (ICRP, 1991) and revised in ICRP Publication 103 (ICRP, 2007), given by:

$$E = \sum_T w_T \sum_R w_R D_{T,R} \text{ or } E = \sum_T w_T H_T$$

where H_T or $w_R D_{T,R}$ is the sex-averaged equivalent dose in tissue or organ T, and w_T is the tissue weighting factor. The SI unit of effective dose is joule per kilogram (J kg^{-1}), and its special name is sievert (Sv).

Effective dose equivalent, H_E The tissue-weighted sum of average dose equivalents in all specified tissues and organs, first defined in ICRP Publication 26 (ICRP, 1977), given by:

$$H_E = \sum_T w_T H_T$$

where w_T is a weighting factor representing the ratio of the stochastic risk resulting from tissue or organ T to the total risk when the whole body is irradiated uniformly and H_T is the average dose equivalent in tissue or organ T. The SI unit of effective dose equivalent is joule per kilogram (J kg^{-1}), and its special name is sievert (Sv). The effective dose equivalent has been superseded by the effective dose.

Electron capture (EC) A form of beta decay in which an atomic electron is captured by the nucleus, thereby transforming a proton into a neutron, and the neutron and a neutrino are emitted from the nucleus. Electron capture always competes with positron (β^+) decay whenever the transition energy is greater than twice the rest-mass energy of an electron (1.022 MeV). See also "beta decay", "positron decay."

Electron volt (eV) The energy gained by an electron or other charged particle carrying unit electronic charge in accelerating through a potential difference of 1 V: $1 \text{ eV} = 1.602 \times 10^{-19} \text{ J}$.

Emergency exposure situation An unexpected situation that occurs during operation of a practice, requiring urgent action.

Environmental radiation standard A source-related restriction on the individual dose, radiation level above background, concentrations of radionuclides in the environment, or release rates or cumulative releases of radionuclides to the environment. See also "dose constraint."

Equivalent dose, H_T The dose in tissue or organ T given by:

$$H_T = \sum_R w_R D_{T,R}$$

where $D_{T,R}$ is the average absorbed dose from radiation R in tissue or organ T, and w_R is the radiation weighting factor. Since w_R is dimensionless, the SI unit of equivalent dose is the same as the SI unit of absorbed dose, J kg^{-1} , and its special name is sievert (Sv).

Existing exposure situation A situation that already exists when a decision on control has to be made, including natural background radiation and residues from past practices that were operated outside requirements for radiation protection.

Exposure (1) A general term often used to indicate an event in which ionizing radiation interacts with a person or other living thing. (2) Term which, in measurement of amounts of ionizing radiation, means the amount of ionic charge produced in a volume of air under specified conditions; see "Roentgen."

External exposure Exposure to ionizing radiation emitted by sources outside the body, including sources deposited on the body surface.

Fission A process in which the nucleus of an atom splits into several parts, including two lighter nuclei and several neutrons, with a release of energy. Fission can be induced by absorption of neutrons in the nucleus of some isotopes of heavy elements, and it occurs spontaneously in decays of several such isotopes.

Fusion A reaction in which two nuclei of low atomic number join together (fuse) to form a heavier nucleus with the release of energy equivalent to the difference between the masses of the two lighter nuclei and the mass of the fusion product.

Gamma ray Highly-penetrating electromagnetic radiation produced in de-excitation of atomic nuclei. See also "photon."

Gray (Gy) The special name for the SI unit of absorbed dose: $1 \text{ Gy} = 1 \text{ J kg}^{-1}$.

Half-life, $T_{1/2}$ The period of time that a radioactive substance takes to decay to half of its initial amount. Measured half-lives can span from microseconds to billions of years. This term also is referred to as the physical or radiological half-life.

Half-value layer (HVL) Thickness of a material required to reduce the intensity of incident radiation by one half.

ICRP (International Commission on Radiological Protection) An independent, charitable, and non-governmental organization created in 1928 to advance the science of radiation protection for the public benefit. The ICRP provides recommendations and guidance on protection against the risks associated with ionizing radiation from artificial sources used in medicine, general industry, and nuclear enterprises and from naturally occurring sources. ICRP recommendations have been incorporated in requirements for radiation protection established by regulatory authorities in many countries.

ICRU (International Commission on Radiation Units and Measurements) An organization formed in 1925 to establish international standards for radiation units and measurement. The ICRU's mission is to develop and promulgate internationally accepted recommendations on radiation related quantities and units, terminology, measurement procedures, and reference data for the safe and efficient application of ionizing radiation to medical diagnosis and therapy, radiation science and technology, and radiation protection of individuals and populations.

Internal conversion (IC) Process of radioactive decay in which a nucleus in an excited state interacts electromagnetically with one of the atom's orbital electrons, resulting in emission of the electron from the atom. Emission of internal conversion electrons always competes with emission of a photon (gamma ray) in de-excitation of excited states of nuclei.

Internal exposure Exposure to ionizing radiation emitted by sources inside the body resulting from intakes of radionuclides by inhalation, ingestion, or absorption through the skin.

Ionizing radiation Radiation—in the form of energetic particles or electromagnetic waves—that can remove electrons from atoms, thereby producing ions and an absorption of energy in a medium.

Isobar Atoms having the same mass number but different atomic number.

Isomeric transition (IT) A type of radioactive decay involving de-excitation of a metastable excited state of an atomic nucleus, called an isomer, to a lower-energy state of the same nucleus by emission of a gamma ray or internal conversion electron. An excited state is considered to be metastable if it exists for a measureable period of time.

Isotone Atoms having the same number of neutrons in their nuclei.

Isotope Atoms having the same number of protons but different numbers of neutrons in their nuclei.

Joule (J) The SI unit of work or energy, equal to the amount of energy exerted when a force of 1 N is applied over a displacement of 1 m. One joule is equivalent to 1 W of power radiated or dissipated for 1 s.

Justification The process of determining whether (1) a planned activity involving radiation is, overall, beneficial, i.e., whether the benefits to individuals and society from introducing or continuing the activity outweigh the harm, including radiation detriment, resulting from the activity; or (2) a proposed remedial action in an emergency or existing exposure situation is likely, overall, to be beneficial, i.e., whether the benefits to individuals and society, including the reduction in radiation detriment, from introducing or continuing the remedial action outweigh its cost and any harm or damage it causes.

Kerma, K The quotient of the sum of the initial kinetic energies of charged particles liberated by uncharged ionizing radiation (i.e., photons and neutrons), $d\epsilon_{tr}$, in matter of mass dm . The SI unit of kerma is joule per kilogram (J kg^{-1}), and its special name is gray (Gy).

$$K = \frac{d\epsilon_{tr}}{dm}$$

Kerma consists of contributions from radiative and collisional processes.

Linear attenuation coefficient, μ The quotient of the fraction of particles that undergo interactions $\left(\frac{dN}{N}\right)$ by the traversed distance in a medium, dl ; a quantity that characterizes the interaction probability of uncharged ionizing radiation (i.e., photons and neutrons) in a medium, as a function of the source radiation, energy, and the density of the medium. The SI unit of the linear attenuation coefficient is m^{-1} .

Linear energy transfer (L or LET) The radiation energy lost per unit path length through a material:

$$L = \frac{d\epsilon}{dl}$$

where $d\epsilon$ is the average energy lost by a charged particle owing to collisions with electrons in traversing a distance dl in matter. The SI unit of L is J m^{-1} , often given in $\text{keV } \mu\text{m}^{-1}$.

Mass attenuation coefficient The quotient of the fraction of particles that undergo interactions $\left(\frac{dN}{N}\right)$ by the traversed distance, dl , within a material having density, ρ , given by $\frac{\mu}{\rho} = \frac{dN}{N\rho dl}$. The mass attenuation coefficient has units $\text{m}^2 \text{kg}^{-1}$.

Mass energy absorption coefficient The product of the fraction of the energy of liberated charged particles lost in radiative processes (g) and the mass energy transfer coefficient μ_{tr}/ρ . The mass energy absorption coefficient, μ_{en}/ρ , has units $\text{m}^2 \text{kg}^{-1}$.

$$\frac{\mu_{en}}{\rho} = (1 - g) \frac{\mu_{tr}}{\rho}$$

Mass energy transfer coefficient The quotient of the fraction of incident radiant energy that is transferred to kinetic energy of charged particles dR_{tr}/R by the traversed distance, dl , within a material having density, ρ , given by $\frac{\mu_{tr}}{\rho} = \frac{dR_{tr}}{R\rho dl}$. The mass energy transfer coefficient, μ_{tr}/ρ , has units $\text{m}^2 \text{kg}^{-1}$.

Maximum permissible dose See "dose limit."

Medical exposure Exposure to ionizing radiation incurred by patients as part of their medical or dental diagnosis or treatment; by persons, other than those occupationally exposed, knowingly while voluntarily helping in the support and comfort of patients; and by volunteers in a program of biomedical research involving their exposure.

Natural background radiation Ionizing radiation that occurs naturally in the environment, including cosmic radiation; radiation emitted by naturally occurring radionuclides in rock, soil, air, and water, including radon except as a decay product of uranium, thorium, or radium in materials subject to requirements for radiation protection; radiation emitted by naturally occurring radionuclides in tissues of organisms; radiation emitted by man-made materials containing incidental amounts of naturally occurring radionuclides (e.g., building materials); and radiation emitted by global fallout from testing of nuclear explosive devices.

NCRP (National Council on Radiation Protection and Measurements) A non-profit corporation chartered by the U.S. Congress in 1964 to collect, analyze, develop, and disseminate in the public interest information and recommendations on (1) protection against radiation and (2) radiation measurements, quantities, and units, particularly those concerned with radiation protection.

Neutron An uncharged particle of mass slightly greater than the mass of a proton that is found in the nucleus of every atom except the isotope of hydrogen with atomic mass number of one.

Nominal risk coefficient Estimates of sex-averaged and age-at-exposure averaged lifetime risks of cancer per unit effective dose equivalent or effective dose in a representative population.

Non-stochastic effect See "tissue reaction."

NORM (naturally occurring radioactive material) Radioactive material containing no significant amounts of radionuclides other than naturally occurring radionuclides. Material in which concentrations of naturally occurring radionuclides have been changed by some process are included in NORM.

Occupational exposure All exposure to ionizing radiation incurred by workers in the course of their work, except for (1) excluded exposures and exposures from exempt activities involving radiation or exempt sources, (2) any medical exposure, and (3) the normal local background radiation.

Operational quantities Quantities used in practical applications for monitoring and investigating situations involving external exposure. They are defined for the purpose of measurement and assessment of dose equivalents in the body from external sources. No operational dose quantities have been defined for the purpose of measurement and assessment of dose equivalents from internal exposure. See also "ambient dose equivalent," "directional dose equivalent," "personal dose equivalent."

Optimization of protection (and safety) The process of determining what level of protection and safety makes exposures to ionizing radiation, and the probability and magnitude of potential exposures, as low as reasonably achievable (ALARA), economic and societal factors being taken into account.

Pair production An absorption process in which an incident photon (gamma ray or X ray) is annihilated in close proximity to an atomic nucleus, producing an electron and positron pair. This process occurs at incident photon energies greater than the rest-mass energy of an electron and positron combined (1.022 MeV).

Personal dose equivalent $H_p(d, \Omega)$ The dose equivalent in soft tissue (commonly interpreted as the "ICRU sphere") at an appropriate depth, d , below a specified point on the human body at an angle of incidence, Ω . The SI unit of personal dose equivalent is joule per kilogram (J kg^{-1}), and its special name is sievert (Sv). The specified point is usually given by the position where the individual's dosimeter is worn. See also "ambient dose equivalent," "directional dose equivalent," and "operational quantity."

Photoelectric effect An absorption process in which an incident photon (gamma ray or X ray) ejects an electron from an atom, with all the photon energy absorbed in ejecting the electron and imparting kinetic energy to it. A characteristic X ray or an Auger electron then is produced when the vacated shell is filled by another orbital electron from a higher shell.

Photon Quantum of electromagnetic radiation, having no charge or mass, that exhibits both particle and wave behavior, such as a gamma ray or X ray.

Photonuclear interaction A process in which a highly energetic photon penetrates the nucleus, resulting in the ejection of a particle, usually a neutron, proton, or alpha particle.

Planned exposure situations Exposure situations involving the planned (routine) operation of sources of ionizing radiation including decommissioning, disposal of radioactive waste, and rehabilitation of previously occupied land. Practices in operation are planned exposure situations.

Planned special exposures Planned exposures to ionizing radiation that occur infrequently, for which allowable doses are in addition to dose limits for routine exposures.

Positron decay A form of beta decay in which a proton in the nucleus of an atom is transformed into a neutron and positron, thereby decreasing the atomic number by one unit, and a positron and a neutrino are emitted from the nucleus. Positron decay occurs only when the transition energy is greater than twice the rest-mass energy of an electron (1.022 MeV). See also "beta decay," "electron capture."

Potential exposure Exposure to ionizing radiation that is not expected to occur with certainty but that may result from an accident at a source or an event or sequence of events of a probabilistic nature, including equipment failures and operating errors.

Principles of radiation protection A set of principles that apply equally to all controllable exposure situations, including: (1) the principle of justification, (2) the principle of optimization, and (3) the principle of application of limits on maximum doses in planned exposure situations.

Protection quantities Dose quantities developed for purposes of radiation protection that allow quantification of the extent of exposure of the human body to ionizing radiation from whole or partial body external irradiation and from intakes of radionuclides. Protection quantities include the average absorbed dose in an organ or tissue, equivalent dose (or average dose equivalent), and effective dose (or effective dose equivalent).

Protective action guides Guidelines on doses that would call for public safety measures, such as evacuation or staying indoors, to reduce or prevent radiation exposure during an emergency. See also "reference level."

Public exposure Exposure to ionizing radiation incurred by members of the public from radiation sources, excluding any occupational or medical exposure and the normal local natural background radiation.

Quality factor, Q A factor characterizing the biological effectiveness of a radiation based on the density of ionization along the tracks of charged particles in tissue. Q is a defined function of the unrestricted linear energy transfer (L or LET) of charged particles in water. The quality factor has been superseded by the radiation weighting factor (w_R) in defining the equivalent dose, but it is still used in calculating dose equivalent quantities (dose equivalents at a point) used in monitoring of external exposure.

Rad The special name for the traditional unit of absorbed dose used prior to introduction of SI units: $1 \text{ rad} = 0.01 \text{ Gy}$.

Radiation detriment A concept, first defined in ICRP Publication 60 (ICRP, 1991) and revised in ICRP Publication 103 (ICRP, 2007), used to quantify the harmful effects of radiation exposure in different parts of the body. Detriment is a defined function of several factors, including (1) incidence of radiation-related cancer or heritable effects, (2) the lethality of those conditions, (3) reduced quality of life, and (4) years of life lost.

Radiation-weighted absorbed dose A quantity analogous to the equivalent dose, in which the radiation weighting factor for high-LET radiations represents the biological effectiveness of those radiations, compared with low-LET radiations, in inducing tissue reactions. These weighting factors are less than values that represent the biological effectiveness of high-LET radiations in inducing stochastic effects.

Radiation-weighting factor, w_R A dimensionless factor, first used in ICRP Publication 60 (ICRP, 1991) and revised in ICRP Publication 103 (ICRP, 2007), by which the average absorbed dose to a tissue or organ from a radiation type of interest is multiplied (modified) to reflect the higher biological effectiveness of high-LET radiations, such as alpha particles, neutrons, and heavy ions, compared with low-LET radiations, such as photons and electrons, in inducing stochastic effects. It is used to derive the equivalent dose from the mean absorbed dose in an organ or tissue.

Radioactive decay See "radioactivity."

Radioactive material Material designated in national law or by a regulatory authority as being subject to regulatory control because of its radioactivity, often taking into account the total activity and activity concentration.

Radioactivity Property or characteristic of an unstable atomic nucleus to spontaneously transform with the emission of energy in the form of ionizing radiation, such as alpha particles, beta particles, gamma rays, and X-rays.

Radioisotope An unstable isotope of an element that decays spontaneously, emitting radiation. Approximately 5000 natural and artificial radioisotopes have been identified.

Reference level In emergency or existing exposure situations, the level of dose or risk, above which it is judged to be inappropriate to plan to allow exposures to occur, and below which optimization of protection should be implemented. The chosen value for a reference level will depend on the prevailing circumstances of the exposure under consideration.

Relative biological effectiveness (RBE) The ratio of a dose of a low-LET reference radiation to the dose of a radiation of interest that gives an identical biological effect. Values of RBE vary with the dose, dose rate, and biological endpoint. In radiation protection, the RBE for stochastic effects at low doses (RBE_M) is of particular interest.

Rem (roentgen equivalent man) The special name for the traditional unit of dose equivalent prior to introduction of SI units: $1 \text{ rem} = 0.01 \text{ Sv}$.

Remedial action level See "reference level."

Risk In the context of health effects associated with exposure to ionizing radiation, the probability that an outcome of interest, such as incidence of cancer, will occur during a specified time period, usually the rest of life, following an exposure.

Roentgen (R) The special name for the traditional unit of exposure to ionizing radiation, defined as the amount of gamma rays or X-rays required to produce one electrostatic unit of positive or negative ionic charge in 1 cm^3 of dry air at standard temperature and pressure. In SI units, $1 \text{ R} = 2.58 \times 10^{-4} \text{ coulomb per kilogram (C kg}^{-1}\text{)}$.

Secular equilibrium A condition involving a long-lived parent radionuclide and its radioactive decay product in which the half-life of the decay product is much shorter (e.g., about 100–1000 times shorter) than the half-life of the parent, and the activities of the parent and its decay product become constant and equal after a time comparable to several half-lives of the decay product. This condition occurs only when the parent is sufficiently long-lived that essentially no decay of the parent takes place during a period of about 10 half-lives of the decay product. See also "transient equilibrium."

Serial decay A series of radioactive decay processes in which a parent radionuclide decays into one (or a successive series) of radionuclides before decaying to a stable isotope.

SI units International system (Système International) of units that define the modern form of the metric system. Base SI units of interest in nuclear energy include: length—meter (m); time—second (s); temperature—kelvin (K); and mass—kilogram (kg). Other base SI units include: amount of a substance—mole (mol); electric current—ampere (A); and luminous intensity—candela (cd). SI units of other quantities, such as energy in joule (J), are defined in terms of base SI units.

Sievert (Sv) The special name for the SI unit of equivalent dose and effective dose: $1 \text{ Sv} = 1 \text{ J kg}^{-1}$.

Source (1) An entity for which radiation protection can be optimized as an integral whole, such as the X-ray equipment in a hospital, or releases of radioactive material from an installation. (2) Sources of radiation, such as radiation generators and sealed radioactive sources, and, more generally, the cause of exposure to radiation or radionuclides.

Stochastic effect Malignant disease (cancer) and heritable effects from exposure to radiation for which the probability of an effect occurring, but not its severity, is regarded as a function of dose without threshold.

Tenth-value layer (TVL) Thickness of a material required to reduce the intensity of incident radiation by a factor of ten.

Threshold dose for tissue reactions Dose estimated to result in only 1% incidence of tissue reactions.

Tissue reaction Radiation-induced injury in populations of cells, characterized by a threshold dose and an increase in the severity of the effect as the dose is increased further. Also called “deterministic effect” or “non-stochastic effect.”

Tissue-weighting factor, w_T A dimensionless factor, defined in ICRP Publication 60 (ICRP, 1991) and revised in ICRP Publication 103 (ICRP, 2007), by which the equivalent dose in tissue or organ T is weighted to represent the relative contribution of that tissue or organ to the total health (radiation) detriment resulting from uniform irradiation of the whole body. The value for each tissue or organ T is weighed such that:

$$\sum_T w_T = 1$$

In calculating the effective dose equivalent, as defined in ICRP Publication 26 (ICRP, 1977), w_T represents the relative contribution of organ or tissue T to the total risk of stochastic effects resulting from uniform irradiation of the whole body.

Transient equilibrium A condition involving a parent radionuclide and its radioactive decay product in which the half-life of the decay product is shorter than the half-life of the parent, and the ratio of the activities of the parent and its decay product, but not their activities, is constant after a time comparable to several half-lives of the decay product. Transient equilibrium differs from secular equilibrium in that (1) significant decay of the parent takes place and (2) the activity of the decay product is greater than the activity of the parent. See also “secular equilibrium.”

Worker Any person who is employed, whether full time, part time, or temporarily, by an employer, and who has recognized rights and duties in relation to occupational radiation protection. See “occupational exposure.”

X-ray (1) Electromagnetic radiation produced in de-excitation of bound atomic electrons, which produces X-rays of discrete energies referred to as characteristic X-rays, or (2) electromagnetic radiation produced in deceleration of charged particles, which produces a continuous energy spectrum of X-rays referred to as bremsstrahlung. See also “photon.”

Ehud Greenspan

University of California at Berkeley
gehud@nuc.berkeley.edu

Professor Greenspan (Ph.D., 1966, in Nuclear Science and Engineering from Cornell University, Ithaca, N.Y., USA) retired from the Department of Nuclear Engineering of the University of California at Berkeley (UCB) in 2014 but served as a Professor in the UCB Graduate School until 2019. He has nearly 60 years of nuclear energy related research experience starting in 1961 as an M.Sc. student at the Department of Nuclear Engineering of the Israel Institute of Technology. His research spans a wide range of nuclear engineering related disciplines including: theoretical and experimental reactor physics; computational methods development including development of new optimization methods for determining the minimum critical mass and for finding optimal design of radiation shields, fusion reactor blankets and medical installations; conception and analysis of advanced fusion fuel cycles and of fusion-fission hybrid reactors; as well as advanced fission reactors and nuclear fuel-cycle conception, design and analysis. The latter activity was the focus of his research during the last twenty-five years. The thrust of this

research is improving sustainability of nuclear energy along with improving economics, safety, and proliferation resistance. He has been the Principal Investigator on studies of dozens of advanced nuclear systems, including those corresponding to Generation-IV reactors and to Small Modular Reactors (SMRs). He was one of the early advocates of SMRs and led a multi-institutional international team that developed a preliminary conceptual design of the Encapsulated Nuclear Heat Source (ENHS)—an innovative nuclear battery-type SMR that is free of pumps, pipes and valves in the primary reactor system. The advanced reactor technologies addressed in his research include: heavy water reactors, pressurized and boiling water reactors, prismatic and pebble-bed liquid-salt cooled reactors, molten-salt reactors, sodium and lead-alloy cooled fast reactors, breed-and-burn reactors, heat-pipe reactors as well as fusion-fission hybrid reactors and accelerator driven nuclear reactors. His research is documented in over 400 refereed publications, over 200 non-refereed publications, 5 book chapters, and a number of patents.

Introduction

From the beginning of the Universe through to the present day, nuclear energy, nuclear reactions, and nuclear radiations have played major roles in the evolution and shaping of our universe and planet Earth. All the chemical elements we find on Earth were produced by nuclear processes in the Universe. Planet Earth is continuously exposed to nuclear radiation from primordial radioactive isotopes produced in cosmological processes that followed the Big Bang. A number of primordial radioactive isotopes are still among the Earth's constituents, including thorium ^{232}Th , the uranium isotopes ^{235}U and ^{238}U as well as potassium ^{40}K . The spontaneous radioactive decay of the nuclides of these isotopes releases nuclear energy that provides a major contribution to the heat balance of planet Earth. The internal heat source is responsible for keeping the outer core of the Earth in a molten magma state and played a major role in the geologic evolution of the Earth's continents and oceans. The primordial radiation and Earth's heat source may have also contributed to the creation as well as evolution of life on Earth. Since its birth, the Earth has been also constantly bombarded by galactic cosmic nuclear radiation, which primarily consists of protons (hydrogen nuclei) and alpha particles (helium nuclei). Hence, mankind as well as any organism on Earth, were and are being continuously exposed to background nuclear radiation throughout their evolution. The background radiation level as well as the radioactive heat source due to the decay of the primordial radioactive isotopes were significantly higher at the time of Earth formation and are slowly decreasing with time.

It is only within the last hundred and twenty years or so that mankind discovered the structure of the atom and its nucleus and learned how to harness the enormous energy potential contained within the nucleus as well as the different types of radiation nuclei and atoms can emit. Nuclear radiation was discovered in 1896, when Henry Becquerel and Marie Curie discovered that salts of uranium emitted radiation that could be detected with photographic plates. In the 125 years since this discovery, mankind deciphered the structure of the atom and its nucleus, learned how to produce artificial radioactive isotopes (Irène Joliot-Curie and Frédéric Joliot in 1934), discovered how to fission certain heavy isotopes (Otto Hahn, Fritz Strassmann, Lise Meitner and Robert Frisch, 1938/39) and learned how to establish a fission chain reaction (Leo Szilard, Enrico Fermi et al., 1942) and developed numerous applications of nuclear radiation and nuclear energy. The feasibility of releasing nuclear energy by fusing nuclei of light isotopes was postulated already in 1920 (Arthur Eddington) who speculated that such nuclear reactions provide the enormous energy released in the sun and stars. Although research of harnessing nuclear fusion for controlled generation of nuclear energy is being pursued since the late 1940s, mankind has not yet succeeded in producing sufficiently more energy from fusion reactions than the energy invested in inducing these reactions. Additional information on the history and fundamentals of harnessing nuclear energy can be found in (Norman, 2021).

Encyclopedia scope

The Encyclopedia of Nuclear Energy (The Encyclopedia) provides a comprehensive authoritative coverage of a wide range of topics related to the generation, utilization and safe handling of nuclear energy, nuclear radiation and associated technologies, for the benefit of mankind and planet Earth. It covers past developments, the present status, and research and development of advanced innovative technologies that may enable improvements in the generation and utilization of nuclear energy (including nuclear radiation). The Encyclopedia consists of 272 thematic articles written by experts and arranged in 13 Sections; each Section covers the subject area identified in Table 1.

The fundamental concept of this encyclopedia is to provide all this vast and very diversified information in convenient to read cross-referenced articles within a single publication. Each article provides an effective solid foundation of its topic and references for readers interested in deeper exploration of the subject matter.

Table 1 Encyclopedia sections, number of articles per section and the section editors.

Sec. #	Section title (# of articles)	Section editor	Section editor affiliation
1	Fundamentals and history of development of nuclear energy (17)	Eric B. Norman	Professor in the Graduate School, Nuclear Engineering Department, University of California at Berkeley
2	Commercial nuclear power reactors and their design (22)	Russell E. Stachowski	Chief Consulting Engineer, Global Nuclear Fuel
3	Advanced nuclear reactor concepts under R&D (28)	Alexander Stanculescu	Retired Generation Four International Forum Technical Director; Retired Idaho National Laboratory Division Director
4	Safety, regulation, and decommissioning of commercial nuclear power reactors (24)	Joy L. Rempe	Rempe and Associates, LLC
5	Fuel cycle front-end: from mining through utilization (17)	Douglas C. Crawford	Director, Transient Reactor Test Facility, Idaho National Laboratory.
		Colby B. Jensen	National Technical Lead for Fuel Safety Research, Idaho National Laboratory
6	Fuel Cycle back-end: from recycling to deep geological disposal (19)	Christophe Poinssot	Deputy General Director (CEO) and Scientific Director of the French Geological Survey (BRGM) ^a
7	Radiation protection (21)	Laurence Miller	Professor Emeritus, Department of Nuclear Engineering, the University of Tennessee
8	Non-electric applications of nuclear energy (15)	Shannon M. Bragg-Sitton	Lead for Integrated Energy Systems, Idaho National Laboratory ^b
9	Nuclear power for space (16)	David I. Poston	Chief Reactor Designer, Los Alamos National Laboratory
10	Research reactors (23)	Sean O'Kelly	Associate Laboratory Director, Idaho National Laboratory. Chair of IAEA Technical Working Group on Research Reactors
11	Medical, industrial and agricultural applications of nuclear technology (26)	Alan E. Waltar	Retired Professor and Head, Department of Nuclear Engineering, Texas A&M University, College Station
12	Nuclear fusion R&D (26)	David J. Campbell	Munich, Germany. Former Director for Science and Operations, ITER Organization
13	Social issues of nuclear energy (18)	Andrew C. Kadak	Kadak Associates, Inc. Former Professor of the Practice Massachusetts Institute of Technology

^aAlso: Prof. of Nuclear Chemistry at the National Institute of Nuclear Science and technology (INSTN).

^balso National Technical Director for the DOE-NE Integrated Energy Systems program.

Intended readership

The articles are written at a level that users, with a bachelor degree in engineering, scientific and medical disciplines, especially in nuclear engineering, will find understandable and helpful. The Encyclopedia is intended to be an invaluable resource for students and will make an important contribution to the preservation of the vast amount of knowhow developed since the dawn of the nuclear era in the nuclear energy related fields and to its transfer to the new generation.

The Encyclopedia will also be very useful to industry and academia researchers and practitioners in the many scientific and engineering fields related to the generation and use of nuclear energy, including nuclear radiation. It will enable researchers and practitioners to refresh their memory in their field of specialization or expand their knowhow on less familiar subject areas.

The Encyclopedia will also be useful to members of the public with education in engineering or sciences who are interested in learning about specific nuclear energy or nuclear radiation related topics without having to struggle with textbooks or journal articles.

On the need for this Encyclopedia

The publication of this Encyclopedia is very timely for a number of reasons, including the following:

- Nuclear energy can play a very important role in drastically reducing the amount of fossil fuels burned for generation of electricity and, hence, the amount of greenhouse gas (GHG; primarily CO₂) emissions while, at the same time, making more electricity available for developing countries and for supporting the expected growth in the world population. Moreover, nuclear energy can make an important contribution to drastically reducing the amount of GHG emission from the transportation, industrial, residential and agricultural sectors of the economy. Hence, nuclear energy can make a vital contribution to meet the goal set by the 2015 Paris Agreement on climate change and ratified by many nations—to limit global warming to well below 2, preferably to 1.5 degrees Celsius, compared to pre-industrial levels. This point is elaborated upon below in the section: “On the Importance of Nuclear Energy in Avoiding Climate Change Catastrophe”. The state of the art in nuclear energy generation is covered in (Stachowski, 2021; Crawford, 2021).

- The Generation IV (GEN-IV) International Forum (GIF) was created in 2001 as a co-operative international endeavor of research, development, demonstration and deployment of advanced fourth generation innovative nuclear reactors that, hopefully, will be available for commercial deployment by 2030. The objectives of the innovative GEN-IV nuclear energy systems include improved sustainability, economics, safety and reliability, as well as proliferation resistance and physical protection. This encyclopedia provides an update on the state of the GEN-IV R&D efforts and explains the benefits the innovative GEN-IV reactors may provide. The Encyclopedia also describes (Stanculescu, 2021) the advanced nuclear fuel cycles that offer highly improved resource utilization, greatly reduced nuclear waste, and reduced proliferation risks.
- Over the past decade or so, there has been a surge in the number of private companies, mostly supported by venture capital, that are developing advanced innovative Small Modular Reactors (SMRs); reactors designed to generate between 10 to 300 MW of electricity per unit (Stanculescu, 2021). The SMRs offer a new paradigm in the generation and delivery of nuclear power; they promise to improve all aspects of design, engineering, construction and operation of commercial nuclear power plants, including enhanced safety performance, better economic affordability, and reduced financial risk. The components (modules) of SMRs are to be of a standard design, shop fabricated in assembly lines subjected to high quality control, and then transported as complete modules to the power plant site for rapid installation. The SMRs also offer flexible power generation for a wider range of users and applications—central power stations can consist of multiple units installed at a rate that best matches the growth in power demand; alternatively, a single SMR unit can be installed in the vicinity of the power customer using a so-called distributed (localized) power grid. It is even being proposed that the hundreds of shuttered coal power plant sites could be repurposed for SMRs. This encyclopedia describes (Stanculescu, 2021) a sample of the SMRs under development and explains the incentives for their development and the benefits they offer. The Encyclopedia also describes the motivation for, and examples of, so called “microreactors”—reactors producing an electrical power of less than 10 MW. Such reactors are primarily intended for deployment in remote areas which are not connected to the grid and to which the transport of fossil fuel is very expensive, as well as to provide reliable power to sensitive installations even in case of failure of the central power grid.
- The very ambitious space explorations being planned by leading industrial countries cannot succeed without nuclear energy. Space Fission Power (SFP) systems offer the potential to enable truly ambitious exploration of outer space, and ultimately a permanent human presence in space. Most of the benefits of SFP is tied to the very high amount of energy that can be extracted per unit weight of fissile material, which can allow high powers and/or long lifetime at a relatively low mass. SFP systems also offer great flexibility in terms of being able to operate in diverse environments, including environments with no or limited solar radiation, and the ability to provide abundant electrical power and heat from kilowatts to megawatts. Applications of SFP include propulsion and/or power for spaceships, electricity and heat for exploration rovers for landing on Mars (other planets and moons) or for human colonies on the Moon or Mars. This encyclopedia describes (Poston, 2021; Bennett, 2021) the many benefits nuclear energy offers to space exploration and the many challenges that need to be overcome.
- Controlled thermonuclear fusion is the focus of major international research programs that aim to demonstrate the scientific and technological feasibility of large-scale generation of nuclear energy by the fusion of light atomic nuclei. The widely distributed fusion fuel resources together with the favorable anticipated safety and environmental characteristics of future fusion power plants provide a significant motivation for the continued development of the challenging science and technology towards the exploitation of fusion energy for the benefit of mankind. In addition to the description of the fundamental elements of the fusion process and of the principal approaches to the controlled and sustained generation of fusion energy being pursued, this Encyclopedia presents the state-of-the-art for fusion research and development and the progress towards commercial fusion energy generation (Campbell, 2021). The advantages and challenges of nuclear fusion as an energy source are summarized.
- This encyclopedia also describes the many ways nuclear radiation can be harnessed to provide enormous benefits in the fields of medicine, agriculture, modern industry, environmental protection, and public safety (Waltar, 2021). Described in the Encyclopedia are more than a dozen unique properties of radiation technology that allow for these benefits to be achieved. Even though enormous and widespread, the benefits to society from these technologies are largely unknown and unappreciated. The global markets for these technologies exceed USA \$500 billion annually and are growing rapidly.
- Also provided in this Encyclopedia is information on dozens of research reactors (O’Kelly, 2021) that are operating or under construction around the world and provide unique research capability for scientists pursuing advanced research in physics, chemistry, biology, material and other sciences. Another invaluable utilization of research reactors is the production of special radioactive isotopes for numerous applications in medical, industrial and agricultural applications, and scientific research. Some research reactors are also used for demonstrating the performance of evolutionary as well as advanced nuclear fuels and of advanced nuclear power reactor components.
- Public perception of nuclear energy varies from country to country. It tends to be most negative in wealthy democracies like Germany, Australia, and Japan. Contributing to the negative perception is a fear of reactor accidents, a fear of nuclear radiation, a fear of long-lived radioactive waste, and a fear of the nuclear technology misuse for weapons proliferation. The encyclopedia addresses these concerns and provides authoritative objective information that, hopefully, will contribute to dispelling the public misconceptions (Kadak, 2021).
- The Encyclopedia describes measures implemented to ensure the health and safety of the public from nuclear power (Rempe, 2021). These measures evolved as new lessons were learned from operating experience and unplanned events, in particular events with core damage and radionuclide release (including in Three Mile Island, Chernobyl, and Fukushima). Clearly, the

experience gained from the design, evaluation, operation, decommissioning, and regulation of nuclear power plants has led to significant safety improvements. Future advanced reactor designs are expected to incorporate innovative inherent safety features (Stanculescu, 2021).

- The encyclopedia provides a detailed description of the biological effects of nuclear radiation, of how we reliably measure radiation levels and ensure that they do not exceed the permissible levels (Miller, 2021). The Encyclopedia describes the theory and practice of radiation protection that provide the basis for regulatory requirements that are essential for the safe and beneficial use of the many advanced technologies that involve exposure to nuclear radiation. The Encyclopedia explains that everyone is exposed to natural background radiation on a daily basis; that radiation is routinely in use for diagnostics of health conditions, such as for dental and medical X-rays, and that this is the largest source of radiation exposure for almost all human population in developed countries and that the benefits from these practices far exceed their risk. The regulatory permissible level of nuclear radiation is harmless much like a moderate exposure to sunshine is harmless (and may even be beneficial, whereas over-exposure can cause sunburns). In other words, the regulatory limits of doses induced by exposure to nuclear radiation are already substantively protective, and there is no evidence of health improvements by reducing the doses below these limits. Insisting to reduce radiation exposure to as low as possible below the regulatory limits may result in harm.
- Also provided in this Encyclopedia is detailed information about the nuclear waste and how it can be disposed of safely (Poinssot, 2021; Kadak, 2021). Using advanced fuel cycles (Stanculescu, 2021; Poinssot, 2021) the amount and activity of the long-lived nuclear waste can be reduced to few percent of the amount that needs to be disposed of per unit of energy generated using the contemporary “once-through” fuel cycle.

On the importance of nuclear energy in avoiding climate change catastrophe

The world’s population is expected to grow from current ~6.7 billion people to over 9 billion by 2050. As recognized in the United Nations Resolution 70/1 “Transforming our world: the 2030 Agenda for Sustainable Development” (Stanculescu, 2021; United Nations, 2015), providing “universal access to affordable, reliable and sustainable energy” and in particular to reliable electrical energy, is central to human development, social stability and even world peace. Currently, about 2.8 billion people are still lacking modern energy services (International Energy Agency, 2017), and more than one billion do not have access to electricity. Not only the growth of worldwide population, but also the economic growth in developing countries will lead to a continuing increase in the demand for energy.

The tremendous increase in energy generation required for the benefit of the global population has to be accomplished while reducing the rate of GHG (primarily CO₂) emission. Already, “human activities are estimated to have caused approximately 1.0 °C of global warming above pre-industrial levels” according to the Intergovernmental Panel on Climate Change (IPCC, 2018). In order to limit the global temperature increase to around 1.5 °C, total CO₂ emissions need to be reduced to net zero by around 2050.

Germany, for example, had decided to achieve this goal by installing renewable energy generators made of solar photovoltaic panels and wind turbines. Germany also decided to close down its nuclear power plants. As a result, according to Goldstein et al. (2019), “Germany, which went all-in for renewables, has seen little reduction in carbon emissions, and, according to our calculations, at Germany’s rate of adding clean energy relative to gross domestic product, it would take the world more than a century to decarbonize, even if the country wasn’t also retiring nuclear plants early. A few lucky countries with abundant hydroelectricity, like Norway and New Zealand, have decarbonized their electric grids, but their success cannot be scaled up elsewhere; the world’s best hydro sites are already dammed.”

Goldstein et al. (2019) are also saying “we actually have proven models for rapid decarbonization with economic and energy growth: France and Sweden. They decarbonized their grids decades ago and now emit less than a tenth of the world average of carbon dioxide per kilowatt-hour. They remain among the world’s most pleasant places to live and enjoy much cheaper electricity than Germany to boot. They did this with nuclear power. And they did it fast, taking advantage of nuclear power’s intense concentration of energy per unit weight of fuel. France replaced almost all of its fossil-fueled electricity with nuclear power nationwide in just 15 years; Sweden, in about 20 years. In fact, most of the fastest additions of clean electricity historically are countries rolling out nuclear power.”

In the words of World Nuclear Association Director General Agneta Rising in 2019 (Bisconti, 2021): “The 445 nuclear reactors in 30 countries are the low-carbon backbone of electricity systems, operating in the background, day in day out, often out of sight and out of mind, capable of generating an immense amount of clean power. They are the silent giants upon which we rely today.” Table 2 lists the fraction of electricity generated during 2018 in selected countries and globally from energy sources that do not emit greenhouse gases (Pioro et al., 2021). According to Poinssot and Bourg (2021), nuclear energy is within the top three of the most environmental-friendly energy sources; in the same range as hydropower and wind-power. Measured by CO₂ emissions, nuclear energy is even the most environmentally friendly energy source.

It is being suggested (Conca, 2021) that recent research has revealed the potential for extracting practically unlimited supplies of uranium from the oceans at a cost that may come close to that of land mining. If successful, this may make fission nuclear energy practically as renewable as wind and solar (Conca, 2021).

It is not sufficient to decarbonize the electricity generation sector. In the U.S., for example, 33% of CO₂ emissions are attributed to energy generated to support the electricity sector but an additional 36% of emissions result from transportation and 19% result

Fig. 2 Conceptualized coordination of energy generation sources and demand to maximize flexibility and economic performance while ensuring grid reliability and resilience.

Most energy experts around the world are advocating the development of a portfolio of low-carbon multi-energy technologies including, in addition to hydro-power plants (with very limited potential for expansion in capacity) and the currently favored “renewable” electricity generators, nuclear power plants. Because the power output of the renewable generators greatly fluctuates over the day and over the year, these generators need to be supplemented by effective energy storage devices that significantly add to the cost of energy.

Nuclear power plants, on the other hand, can generate power at a constant rate throughout the day and the year (excluding a shutdown period of ~1 month for refueling and maintenance once every 18–24 months), practically independent of weather conditions, while requiring a smaller land area per unit energy generated relative to the area required by renewable energy generators.

Moreover, nuclear energy can be generated in the form of high temperature heat (Stanculescu, 2021; Bragg-Sitton and Boardman, 2021) that is the most economical form of energy to store and to use as a backup for the intermittent nature of the renewable energy generators. Therefore, a suitable mix of nuclear and renewables is likely to be the optimal strategy for carbon-free energy generation.

Fig. 1 (Bragg-Sitton and Boardman, 2021) is a simplified illustration of the evolving perception of integrated energy systems using contemporary nuclear power reactors (primarily Light Water Reactors, LWR) in combination with solar and wind renewable energy generators to provide electricity and heat energy for transportation and many industries including non-grid energy users.

Fig. 2 (Bragg-Sitton et al., 2021) is a simplified conceptual perception of the proposed transition away from the use of contemporary large central nuclear power plants from their traditional electricity-only production mode to their exploitation for the provision of a variety of outputs. Future energy systems that seek to maximize energy utilization, generator profitability, and grid reliability and resilience must necessarily consider all available carbon-free energy sources, using each available resource in a way that maximizes its benefits while minimizing less-desirable attributes. The future energy systems should include advanced nuclear reactors including Gen-IV reactors, SMRs and even microreactors and should use distributed in addition to centralized electricity grids.

In summary, the need to meet the objective of zero net CO₂ emission by 2050 combined with the need to greatly increase the total global energy generation rate is an enormous challenge that can be achieved only by making use of all available clean energy generation technologies including nuclear in addition to solar and wind electricity generators. At the 2021 Earth Day climate summit, U.S. president Biden called (WSJ, 2021) for slashing U.S. greenhouse gas emissions by 2030 by 50%–52% compared with the baseline year of 2005, as he seeks to put America at the forefront of world-wide efforts to combat climate change. According to WSJ (2021), meeting this objective would require dramatically reshaping key sectors of the economy, from energy to transportation to agriculture.

Concluding remarks

This Encyclopedia of Nuclear Energy provides a very comprehensive, up-to-date and authoritative information related to nuclear energy, including nuclear radiation—from the discovery of the structure of the atom and its nucleus; through the discovery of three different ways to extract energy from nuclei (fission of heavy nuclei, fusion of light nuclei and radioactive decay); through the state-of-art of the nuclear industry for energy generation and for exploitation of several nuclear technologies for medical, industrial, agricultural and other applications; to the research and development of innovative nuclear technologies that are expected to further

increase mankind benefits from nuclear energy. The reader can find in the Encyclopedia a wide range of topics ranging from the contribution of nuclear energy to the evolution of the continents and oceans of planet Earth to the enabling of very ambitious space explorations including the provision of electricity and heat to human colonies on the Moon, Mars and beyond. The Encyclopedia explains why it is essential to greatly increase the nuclear energy generation rate in order to prevent a global warming catastrophe and, at the same time, provide sufficient energy to the growing world population and to the billions of people in underdeveloped countries.

It is hoped that this Encyclopedia will make an important contribution to transferring of the huge amount of technical knowledge accumulated in the field to the young generation, will inspire students to join research and development of innovative nuclear technologies and will contribute to better understanding of the nuclear technologies, their merits and safety by the general public and policy makers. The appreciation of the enormous benefits in the fields of steady reliable clean energy generation, medicine, agriculture, modern industry, environmental protection, and public safety that mankind enjoys every day and which is described in this Encyclopedia will, hopefully, contribute to much greater public acceptance and support of enhanced utilization of nuclear energy in the mix of clean energy technologies.

Acknowledgments

The Editor-in-Chief is very thankful to the Editors of the 13 sections of this encyclopedia who worked very hard and with dedication to compose the scope of their sections, find expert authors for each of their section articles and finally review and revise these articles. Many thanks are also due to the several hundred authors of the encyclopedia articles who agreed to share their expert know-how with the readers. The support provided by the Encyclopedia Content Project Manager Natalie Lovell, by the Associate Content Project Manager, Gayathri S and their staff is highly appreciated.

Eggenstein-Leopoldshafen, Germany*

Shannon M Bragg-Sitton

*Idaho National Laboratory (INL), Idaho Falls, ID,
United States*

Jeffrey Brown

*Arizona Public Service (APS), Phoenix, AZ, United
States*

Haydn C Bryan

*Idaho National Laboratory, Idaho Falls, ID, United
States*

David J Campbell

Munich, Germany

E Michael Campbell

*Laboratory for Laser Energetics, University of Rochester,
Rochester, NY, United States*

Gustavo P Canal

*Institute of Physics, University of São Paulo, São Paulo,
Brazil*

JW Coenen

*Forschungszentrum Jülich GmbH, Institut für Energie-
und Klimaforschung, Jülich, Germany; and Department
of Engineering Physics, University of Wisconsin
Madison, Madison, WI, United States*

Valentina Corato

ENEA, C.R. Frascati, Rome, Italy

Christian Day

*Karlsruhe Institute of Technology (KIT), Eggenstein-
Leopoldshafen, Germany*

MR Deinert

*Associate Professor, Department of Mechanical
Engineering, Nuclear Science and Engineering,
Colorado School of Mines, Golden, CO, United States*

Brian D Dold

*Idaho National Laboratory, Idaho Falls, ID, United
States*

AJH Donné

EUROfusion, Garching, Germany; and Dutch Institute for Fundamental Energy Research, Eindhoven, The Netherlands

RJ Dumont

CEA, IRFM, Saint-Paul-lez-Durance, France

Mike Dunne

SLAC National Accelerator Laboratory, Stanford University, Menlo Park, CA, United States

I Duran

Institute of Plasma Physics of the Czech Academy of Sciences, Praha, Czech Republic

Amgad Elgowainy

Energy Systems Division, Argonne National Laboratory, Lemont, IL, United States

Aaron S Epiney

Idaho National Laboratory (INL), Idaho Falls, ID, United States

Gianfranco Federici

Fusion for Energy, Garching, Germany

SM Finnegan

Los Alamos National Laboratory, Los Alamos, NM, United States

Charles W Forsberg

Massachusetts Institute of Technology, Cambridge, MA, United States

Andrew W Foss

Idaho National Laboratory, Idaho Falls, ID, United States

Konor L Frick

Idaho National Laboratory (INL), Idaho Falls, ID, United States

Ricardo MO Galvão

Institute of Physics, University of São Paulo, São Paulo, Brazil

Yu Gasparyan

National Research Nuclear University MEPhI, Moscow, Russian Federation

MR Gilbert

United Kingdom Atomic Energy Authority, Culham Science Centre, Abingdon, Oxfordshire, United Kingdom

Matthew R Gomez

Sandia National Laboratories, Albuquerque, NM, United States

NN Gorelenkov

Princeton Plasma Physics Laboratory, Princeton, NJ, United States

Cassandra Graham

Beyond NERVA, Dayton, OH, United States

Nils H Haneklaus

Danube University Krems, Krems an der Donau, Austria; and Freiberg University of Mining and Technology, Freiberg, Germany

J Stephen Herring

Center for Space Nuclear Research, Universities Space Research Association, LLC, Idaho Falls, ID, United States

Jamie Holladay

Pacific Northwest National Laboratory, Richland, WA, United States

E Hollmann

University of California—San Diego, La Jolla, CA, United States

Steven D Howe

Howe Industries LLC, Scottsdale, AZ, United States

A Ibarra

CIEMAT, Madrid, Spain

Ryota Imazawa

National Institutes for Quantum and Radiological Science and Technology (QST), Naka Fusion Research Institute, Ibaraki-ken, Japan

Takashi Inoue

National Institutes for Quantum and Radiological Science and Technology (QST), Naka Fusion Research Institute, Ibaraki-ken, Japan

Frank Jenko

Max Planck Institute for Plasma Physics, Garching, Germany

Jeromy Jenks

Pacific Northwest National Laboratory, Richland, WA, United States

Samuel Jimenez

CCFE Culham Science Centre, Abingdon, United Kingdom

L Todd Knighton

Idaho National Laboratory, Idaho Falls, ID, United States

Kenichi Kurihara

National Institutes for Quantum and Radiological Science and Technology (QST), Naka Fusion Research Institute, Ibaraki-ken, Japan

Lang L Lao
General Atomics, San Diego, CA, United States

Shuyun Li
Pacific Northwest National Laboratory, Richland, WA, United States

Ch Linsmeier
Forschungszentrum Jülich GmbH, Institut für Energie- und Klimaforschung, Jülich, Germany

A Litnovsky
Forschungszentrum Jülich GmbH, Institut für Energie- und Klimaforschung, Jülich, Germany; and National Research Nuclear University MEPhI, Moscow, Russian Federation

Xinyu Liu
Energy Systems Division, Argonne National Laboratory, Lemont, IL, United States

YQ Liu
General Atomics, San Diego, CA, United States

So Maruyama
ITER Organization, Saint-Paul-lez-Durance, France

Patrick R McClure
Los Alamos National Laboratory, Los Alamos, NM, United States

Michael G McKellar
University of Idaho, Idaho Falls, ID, United States

Wayne Meier
Lawrence Livermore National Laboratory, Livermore, CA, United States

J Menard
Princeton Plasma Physics Laboratory, Princeton, NJ, United States

Christopher Morrison
Astro Nuclear Engineer, USNC-Tech, Seattle, WA, United States

S Nogami
Department of Quantum Science & Energy Engineering, Graduate School of Engineering, Tohoku University, Sendai, Japan

Jose Manuel Perlado
Instituto Fusión Nuclear “Guillermo Velarde”, Universidad Politecnica Madrid, UPM, Spain

Steven Phillips
Pacific Northwest National Laboratory, Richland, WA, United States

David I Poston
Los Alamos National Laboratory, Los Alamos, NM, United States; and Space Nuclear Power Corporation, Los Alamos, NM, United States

Cristian Rabiti
Idaho National Laboratory (INL), Idaho Falls, ID, United States

Sean P Regan
Laboratory for Laser Energetics, University of Rochester, Rochester, NY, United States

Susana Reyes
SLAC National Accelerator Laboratory, Stanford University, Menlo Park, CA, United States

Gregory A Rochau
Sandia National Laboratories, Albuquerque, NM, United States

Javier Sanz Gozola
Instituto Fusión Nuclear “Guillermo Velarde”, Universidad Politecnica Madrid, UPM, Spain; and Departamento de Ingeniería Energética, Universidad Nacional de Educación a Distancia, UNED, Spain

Yanick Sarazin
CEA, IFRM, Saint-Paul-lez-Durance, France

AE Schweikert
Research Assistant Professor, Department of Mechanical Engineering, Nuclear Science and Engineering, Colorado School of Mines, Golden, CO, United States

Peter A Seidl
Lawrence Berkeley National Laboratory, Berkeley, CA, United States

SE Sharapov
CCFE, Culham Science Centre, Abingdon, United Kingdom

Daniel B Sinars
Sandia National Laboratories, Albuquerque, NM, United States

CH Skinner
Princeton Plasma Physics Laboratory, Princeton, NJ, United States

Stephen A Slutz
Sandia National Laboratories, Albuquerque, NM, United States

Lesley Snowden-Swan
Pacific Northwest National Laboratory, Richland, WA, United States

Hong Yong Sohn

*Department of Materials Science & Engineering,
University of Utah, Salt Lake City, UT, United States*

Pingping Sun

*Energy Systems Division, Argonne National Laboratory,
Lemont, IL, United States*

Sellathurai(Sam) Suppiah

*Canadian Nuclear Laboratories Ltd., Chalk River, ON,
Canada*

Mary Ann Sweeney

*Sandia National Laboratories, Albuquerque, NM,
United States*

Koji Takahashi

*National Institutes for Quantum and Radiological
Science and Technology (QST), Naka Fusion Research
Institute, Ibaraki-ken, Japan*

Neill P Taylor

*UK Atomic Energy Authority, Culham Science Centre,
Abingdon, United Kingdom*

Vladimir T Tikhonchuk

*CELIA, University of Bordeaux, CNRS, CEA, Talence,
France; and ELI-Beamlines, Institute of Physics, Czech
Academy of Sciences, Dolní Břežany, Czech Republic*

Hiroyuki Tobari

*National Institutes for Quantum and Radiological
Science and Technology (QST), Naka Fusion Research
Institute, Ibaraki-ken, Japan*

Michael Tobin

*Johns Hopkins University Applied Physics Laboratory,
Air and Missile Defense Systems, Laurel, MD, United
States*

Alan D Turnbull

General Atomics, San Diego, CA, United States

Susan S Voss

*Global Nuclear Network Analysis, LLC, Taos, NM,
United States*

Mickey Wade

*Oak Ridge National Laboratory, Oak Ridge, TN, United
States*

F Warmer

*Max-Planck Institute for Plasma Physics, Greifswald,
Germany*

Daniel S Wendt

*Idaho National Laboratory, Idaho Falls, ID, United
States*

Hiroshi Yamada

*Graduate School of Frontier Sciences, The University of
Tokyo, Kashiwa, Chiba, Japan*

Jeong-Ha You

*Max Planck Institute for Plasma Physics, Garching,
Germany*

S Zinkle

University of Tennessee, Knoxville, TN, United States

Hartmut Zohm

*Max-Planck-Institute for Plasma Physics, Garching,
Germany*

M Zuin

*Consorzio RFX (CNR, ENEA, INFN, Università di
Padova, Acciaierie Venete SpA), Padova, Italy*

CONTENTS OF ALL VOLUMES

<i>Editorial Board</i>	<i>v</i>
<i>Editor-In-Chief</i>	<i>vii</i>
<i>Introduction to the Encyclopedia of Nuclear Energy</i>	<i>ix</i>
<i>Contributors to Volume 3</i>	<i>xvii</i>

VOLUME 1

Fundamentals and History of Development of Nuclear Energy

Introduction to Fundamentals and History of Development of Nuclear Energy <i>Eric B Norman</i>	1
What Is the Universe Made of? <i>Alejandro Garcia</i>	3
Discovery of Radioactivity <i>Daniel E DiGregorio</i>	9
Discovery of the Quantum Structure of Atoms and Their Nuclei <i>Kenneth S Krane</i>	19
Origins of Nuclear Energy <i>Jim Napolitano</i>	29
Radioactive Decay <i>E Previtali</i>	35
Nuclear Fission I <i>Jennifer L Klay</i>	45
Nuclear Fission II <i>Andrew E Stuchbery</i>	53
Fissile and Fertile Fuels <i>Jennifer Shusterman</i>	66
Manhattan Project <i>B Cameron Reed</i>	78

Nuclear Fusion <i>Edward C Morse</i>	92
Atomic and Hydrogen Bombs <i>Jim Napolitano</i>	101
Phenomenology of Neutron Interactions <i>Fred E Wietfeldt</i>	107
Phenomenology of Gamma Ray and Charged Particles Interactions <i>Reina Maruyama</i>	117
Radiation Sources <i>David K Wehe</i>	125
Experimental Tools I: Radiation Detectors <i>Ke Han</i>	133
Experimental Tools II: Particle Accelerators <i>Alejandro Garcia</i>	146
Commercial Nuclear Power Reactors and their Design	
Commercial Nuclear Power Reactors and Their Design—Introduction <i>Russell E Stachowski</i>	153
History of PWR and BWR Development <i>Jeffery A Brown and G Ivan Maldonado</i>	157
Physics of the Fission Chain Reaction in Thermal and Fast Reactors <i>Pavel V Tsvetkov and Russell E Stachowski</i>	172
Principles of Design and Operation of Nuclear Power Reactors <i>David A Hamon</i>	187
Pressurized Water Reactors <i>Jeffery A Brown</i>	196
Boiling Water Reactors <i>David A Hamon</i>	214
Heavy-Water Reactors <i>Eleodor Nichita</i>	236
Commercial Nuclear Power Plant Statistics <i>David A Hamon</i>	252
Pros and Cons of Commercial Reactor Designs Part 1: Current Status of Electricity Generation in the World and Selected Countries <i>I Pioro, RB Duffey, PL Kirillov, and R Pioro</i>	263
Pros and Cons of Commercial Reactor Designs: Part 2—Current Status and Future Trends in the World Nuclear-Power Industry and Technical Considerations of Nuclear-Power Reactors <i>I Pioro, RB Duffey, PL Kirillov, and R Pioro</i>	288
Economics of Nuclear Energy <i>Geoffrey S Rothwell</i>	304

Economic Challenges of Nuclear Energy <i>Geoffrey S Rothwell</i>	317
Fuel Rod, Fuel Assembly, and Reactivity Control Assembly Design <i>Michael Y Young</i>	327
Heat Transfer Systems <i>Karen Vierow Kirkland</i>	345
Instrumentation and Control Systems of Nuclear Power Plants <i>Belle R Upadhyaya and Richard T Wood</i>	373
Reactor Operations <i>Michael Y Young</i>	393
Operational Analysis Methods <i>William Walters</i>	405
Transient Analysis Methods <i>RP Martin</i>	422
Containment <i>Phil Sharpe</i>	439
Design of the Balance of Plant <i>M Arcaro</i>	446
Safety of Nuclear Reactors <i>Nicholas R Brown and Seok Bin Seo</i>	456
Management of the Nuclear Waste – Via Disposition or Transmutation <i>Pavel V Tsvetkov</i>	465
Advanced Nuclear Reactor Concepts Under R&D	
Worldwide Status of Advanced Reactors (GEN IV) Research and Technology Development <i>Alexander Stanculescu</i>	478
Sodium-Cooled Fast Reactors <i>F Heidet</i>	490
The High Temperature Gas-Cooled Reactor <i>Michael A Fütterer, Gerhard Strydom, Hiroyuki Sato, Fu Li, Eric Abonneau, Tim Abram, Mike W Davies, Minwhan Kim, Lyndon Edwards, Ondrej Muransky, Manuel A Pouchon, and Metin Yetisir</i>	512
Lead Cooled Fast Reactors <i>Alessandro Alemberti</i>	523
Gas Cooled Fast Reactor System (GFR) <i>Branislav Hatala</i>	545
Molten Salt Reactors <i>Victor V Ignatiev</i>	553
Super-Critical Water-Cooled Reactor (SCWR) <i>Yanping Huang, Jinguang Zang, and Laurence Kim-Hung Leung</i>	569
Advanced Light Water-Cooled Reactor Concepts <i>Eugene Shwageraus</i>	582

Fluoride-Salt-Cooled High-Temperature Reactors <i>Massimiliano Fratoni</i>	602
Introduction to Breed and Burn Reactors <i>Staffan Qvist</i>	609
Molten Chloride Fast Reactors (MCFRs) <i>Jiri Krepel and Kevin J Kramer</i>	625
Traveling Wave Reactor (TWR [®]) <i>Pavel Hejzlar</i>	643
CANDLE Reactor Concept <i>Hiroshi Sekimoto</i>	657
A Seed-Driven Breed-and-Burn Blanket Core Concept <i>E Greenspan</i>	673
Worldwide Status of Small Reactors Research and Technology Development <i>Frederik Reitsma and M Hadid Subki</i>	685
Water Cooled Small Modular Reactors (Integral PWR and BWR) <i>M Hadid Subki</i>	694
Floating Nuclear Power Plants With Small Modular Reactors <i>M Hadid Subki</i>	711
Pebble Bed Gas Cooled Reactors <i>Frederik Reitsma</i>	721
Heavy Liquid Metal (HLM) Cooled Fast Small Modular Reactors <i>Craig F Smith</i>	732
Micro-Reactors <i>Janne Wallenius</i>	749
Light Water Reactors (LWR) Fuel Cycle Options <i>Eugene Shwageraus</i>	757
Advanced Fuel Cycles Identification and Evaluation <i>R Wigeland, T Taiwo, M Todosow, W Halsey, and J Gehin</i>	771
Self-Sustaining Breeding in Advanced Reactors: Characterization of Natural Resources <i>Jiri Krepel</i>	786
Self-Sustaining Breeding in Advanced Reactors: Characterization of Selected Reactors <i>Jiri Krepel and Evzen Losa</i>	801
Self-Sustaining Breeding in Advanced Reactors: Comparison of Fuel Cycle Performance <i>Jiri Krepel</i>	820
Advanced Modeling and Simulation Methods <i>Carlo Fiorina</i>	837
Additive Manufacturing in the Nuclear Reactor Industry <i>Benjamin R Betzler</i>	851
New Reactor Concepts Deployment Challenges and Opportunities <i>Ramesh Sadhankar</i>	864

VOLUME 2

Safety, Licensing and Decommissioning of Power Reactors

Safety, Regulation, and Decommissioning of Commercial Nuclear Power Reactors—Introduction <i>Joy L Rempe</i>	1
Safety Lessons From Two Events Without Core Damage <i>Joy L Rempe</i>	6
The Three Mile Island Unit 2 Accident <i>Gordon R Skillman and Joy L Rempe</i>	17
The Chernobyl Nuclear Power Plant Unit-4 Accident <i>Alexander R Sich</i>	30
The Events at Fukushima Daiichi <i>Shinya Mizokami and Joy L Rempe</i>	53
Ensuring Safety by Design and Evaluation <i>Joy L Rempe</i>	67
Reactor Protection System <i>Robert Lutz and Bill Williamson</i>	76
Engineered Safety Features <i>Robert Lutz and Bill Williamson</i>	88
Instrumentation and Control <i>Robert Lutz and Bill Williamson</i>	99
Guidance for Operating Within Design Basis Conditions <i>Robert Lutz and Bill Williamson</i>	108
Beyond Design Basis Event Considerations <i>Robert Lutz and Bill Williamson</i>	115
Safety Evaluations <i>RO Gauntt</i>	126
Overview of Nuclear Regulation and Regulatory Framework <i>Joy L Rempe and Laurence G Williams</i>	139
U.S. Regulation and Licensing—Historical Perspective <i>Dennis C Bley and Marty Malsch</i>	150
U.S. Regulations for Commercial Nuclear Power Plants <i>Dennis C Bley and Marty Malsch</i>	163
U.S. Options for Licensing a New Commercial Power Plant <i>Harold B Ray</i>	168
Regulation of Two U.S. Non-LWRs—Lessons Learned <i>Joy L Rempe</i>	175
Overview of International Nuclear Safety Regulation and Licensing <i>Laurence G Williams</i>	188
Probabilistic Risk Assessment <i>Mohammad Modarres and Inn Seock Kim</i>	207

Regulatory Applications of Risk Assessment <i>Donald A Dube</i>	218
Risk Assessment Insights and Impact <i>Karl N Fleming</i>	227
Nuclear Power Plant Decommissioning <i>Rod McCullum</i>	240
SAFSTOR Decommissioning Example (Kewaunee) <i>Rod McCullum</i>	247
DECON Decommissioning Example (Maine Yankee) <i>Rod McCullum</i>	251
The Nuclear Fuel and Fuel Cycle	
Introduction to Fuel Cycle Front End: From Mining Through Utilization <i>Douglas C Crawford</i>	255
Uranium Resources <i>Ian Hore-Lacy</i>	265
Uranium Extraction From Seawater Makes Nuclear Power Virtually Renewable <i>James L Conca</i>	277
Unconventional Uranium Resources From Phosphates <i>Nils H Haneklaus</i>	286
Uranium Conversion and Enrichment <i>Patrick Hogan</i>	292
Fuel Design and Fabrication: Pellet-Type Fuel <i>Masato Kato</i>	298
Fuel Design and Fabrication: Fast-Reactor Metal Fuels <i>Douglas L Porter and Douglas C Crawford</i>	308
Fuel Design and Fabrication: TRISO Particle Fuel <i>Grant W Helmreich and John D Hunn</i>	318
Fuel Design and Fabrication: Research Reactor Fuel <i>James I Cole, Jan-Fong Jue, and Glenn A Moore</i>	326
Nuclear Criticality Safety <i>Douglas G Bowen</i>	334
Fresh Fuel Properties: Ceramic Compounds <i>Giovanni Pastore and Aysenur Toptan</i>	343
Zr-Alloyed Metallic Fuel Properties <i>Stephen Novascone, Christopher Matthews, Albert Casagrande, Aysenur Toptan, and Adam Zabriskie</i>	356
Molten Salt Fuels: Properties, Purification, and Corrosion Control <i>Ruchi Gakhar, William C Phillips, Guoping Cao, Tae-Sic Yoo, Michael E Woods, Guy L Fredrickson, and Toni Karlsson</i>	366
Irradiation Performance: Light Water Reactor Fuels <i>Paul Cantownine and Bob Rand</i>	377

Irradiation Performance: Fast Reactor Fuels <i>Colby B Jensen and Nicolas E Woolstenhulme</i>	392
Irradiation Performance: High-Temperature Gas Reactor Fuels <i>Tyler J Gerczak</i>	407
Irradiation Performance: Research Reactor Fuels <i>James I Cole, Hakan Ozaltun, Jan-Fong Jue, Warren F Jones, Dennis D Keiser, Jr, Barry Rabin, and Mitchell K Meyer</i>	420
The Nuclear Waste and its Disposal	
Key Characteristics of Used Nuclear Fuel <i>J-P Glatz</i>	429
Fuel Storage (New Fuel/Used Fuel Pool) <i>John H Kessler</i>	441
The Chemical Basis for Separating Recycling Materials by Hydro-Processes <i>Robin Taylor</i>	450
The Chemical Basis for Separating Recycling Materials by Pyro-Processes <i>Stéphane Bourg</i>	465
The Current Industrial Mono-Recycling of U and Pu: Reprocessing Step <i>Gérald Senentz</i>	482
The Current Industrial Mono-Recycling of U and Pu: Recycling Step <i>Jean-Michel Marin</i>	494
Routes for Pu Multi-recycling <i>Bernard Boullis and Christine Chabert</i>	510
The Adaptation of Recycling Processes to Pu-Multi Recycling <i>Manuel Miguiriditchian and Robin Taylor</i>	523
Effluent Decontamination <i>V Blet</i>	534
ILW conditioning and performance <i>Samuel A Walling, Laura J Gardner, and Neil C Hyatt</i>	548
HLW Conditioning and Long-Term Performance <i>Florence Bart, Christophe Poinssot, Stéphane Gin, Sylvain Peuget, and Céline Roussel</i>	564
Spent nuclear fuel long term behavior and performance <i>Bernd Grambow</i>	577
The Concept of Geological Disposal of Highly Radioactive Nuclear Waste <i>Rodney C Ewing and Sulgiye Park</i>	588
Radionuclide Migration in the Context of High-Level Nuclear Waste Management <i>Jordi Bruno</i>	603
Main Repository Projects Worldwide <i>Soufiane Mekki</i>	616
Actinide Immobilization in Dedicated Wasteforms: An Alternative Pathway for the Long-Term Management of Existing Actinide Stockpiles <i>Lewis R Blackburn and Neil C Hyatt</i>	650

Potential Fuel Cycle Back-End for Thorium Fuel Cycle <i>Xiangzhou Cai and Zhiguang Wang</i>	663
Assessment of the Relative Environmental Footprint of Nuclear Energy and Its Fuel Cycle <i>Ch Poinssot and S Bourg</i>	675
Social Acceptability of Geologic Disposal <i>Daniel S Metlay</i>	684
Radiation Protection	
Radiation Protection – Introduction <i>Laurence Miller</i>	698
Ionizing Radiation: Discovery and Dose Quantities <i>Shaheen Azim Dewji</i>	701
Fundamentals of Health Physics <i>Shaheen Azim Dewji and Laurence Miller</i>	716
Natural and Man-Made Sources of Radiation <i>Laurence Miller, A Iulian Apostoaei, Michael Howard, and Vikram Singh</i>	744
Source Terms for Nuclear Reactors Operations, Accidents, and Waste <i>Vikram Singh and Alexander M Wheeler</i>	765
External Dosimetry <i>Ken G Veinot</i>	777
Internal Dosimetry <i>Lisa M Snapp and Keith F Eckerman</i>	790
Instrumentation and Practices for Radiological Assessments <i>Timothy J Vitkus, David A King, Nick A Altic, and Wade P Ivey</i>	803
Emergency Response <i>Craig M Marianno</i>	828
Standards to Control Radiation Exposures of Workers and the Public <i>David C. Kocher</i>	840
Risk Tradeoff Analysis <i>TW Hansen, Jr</i>	851
Computer Codes for Determining Acceptable Levels of Contamination <i>John Arnish</i>	858
Characterization and Release of Contaminated Sites <i>Timothy J Vitkus</i>	869
Radiological Control Practices <i>TW Hansen, Jr</i>	890
Radiation Shielding Methods <i>Ronald Pevey</i>	899
Shielding Against Galactic and Solar Radiation in Space <i>Lawrence Heilbronn</i>	914
Health Effects and Radiation Biology <i>Trent L Nichols and Thomas Byrne</i>	923

Estimation of Health Risks From Exposure to Ionizing Radiation <i>A Iulian Apostoaiei</i>	937
Drones for Radiological Assessment <i>Alexandra C Hackett</i>	950
An Illustrative Example of Microdosimetry—Boron Neutron Capture Therapy for Cancer <i>Trent L Nichols</i>	958
Radiation Protection: Glossary of Terms <i>Shaheen Azim Dewji, David C Kocher, and Sherry Adadi</i>	981

VOLUME 3

Non-Electric Applications of Terrestrial Nuclear Reactors

Introduction to Nonelectric Applications of Nuclear Energy <i>Shannon M Bragg-Sitton and Richard D Boardman</i>	1
District Heating and Nuclear Power <i>AE Schweikert and MR Deinert</i>	8
Nuclear Driven Water Desalination <i>Aaron S Epiney, Konor L Frick, Cristian Rabiti, Jeffrey Brown, and Shannon M Bragg-Sitton</i>	17
Nuclear-Supported Electrification of the Transportation Sector <i>Xinyu Liu, Adarsh Bafana, Pingping Sun, and Amgad Elgowainy</i>	25
Heat Pumps Driven by Zero-Carbon Electricity <i>J Stephen Herring</i>	34
Coupling Heat Storage to Base-Load Nuclear Reactors for Variable Heat, Electricity and Hydrogen <i>Charles W Forsberg</i>	40
Process Heat for Chemical Industry <i>Richard D Boardman, Michael G McKellar, Brian D Dold, Andrew W Foss, and Haydn C Bryan</i>	49
Industrial Processes for Grid Stabilization <i>Frédéric Bienvenu</i>	61
Thermochemical Hydrogen Production <i>Sellathurai(Sam) Suppiah</i>	73
High Temperature Steam Electrolysis <i>Richard D Boardman</i>	82
Synthetic Hydrocarbon Fuels From H ₂ and Captured CO ₂ <i>Lesley Snowden-Swan, Shuyun Li, Jeromy Jenks, Steven Phillips, Jalal Askander, Jamie Holladay, L Todd Knighton, and Daniel S Wendt</i>	94
Ammonia Synthesis <i>Richard D Boardman</i>	113
Hydrogen-Based Flash Ironmaking Technology (HyFIT): A Novel Green Ironmaking Technology With Low Energy Consumption <i>Hong Yong Sohn</i>	122

Calcination	131
<i>Nils H Haneklaus</i>	
Marine Propulsion	139
<i>Anil Kumar Anand and J Stephen Herring</i>	
Nuclear Power for Space and Propulsion	
Introduction to Space Nuclear Power and Propulsion	155
<i>Gary L Bennett</i>	
Radioisotope Power: Benefits and Challenges	168
<i>Gary L Bennett</i>	
Radioisotope Power: Historical Review	174
<i>Gary L Bennett</i>	
Radioisotope Power: Technology Options	191
<i>Gary L Bennett</i>	
Space Fission Power: Benefits and Challenges	201
<i>David I Poston</i>	
Space Fission Power: Historical Review	213
<i>Susan S Voss</i>	
Space Fission Power: Technology Options – Reactor Core	223
<i>David I Poston</i>	
Space Fission Power: Technology Options—Heat Transport	237
<i>David I Poston</i>	
Space Fission Power: Technology Options—Radiation Shielding	250
<i>David I Poston</i>	
Space Fission Power: Kilopower and KRUSTY	266
<i>David I Poston</i>	
Nuclear Thermal Propulsion: Benefits and Challenges	280
<i>David I Poston</i>	
The History of Nuclear Thermal Rocket Development	290
<i>Cassandra Graham</i>	
Nuclear Thermal Propulsion: Technology Options	303
<i>David I Poston</i>	
Nuclear Electric Propulsion for Rapid Transportation Within the Solar System	321
<i>Christopher Morrison</i>	
Advanced Propulsion: Pulsed, Fusion, Antimatter and Breakthrough Physics	343
<i>Steven D Howe</i>	
Space Nuclear Power Safety and Safeguards	352
<i>Patrick R McClure</i>	
Nuclear Fusion R&D	
Nuclear Fusion – Introduction and Overview	358
<i>David J Campbell</i>	

Magnetic Confinement Fusion—Principles <i>Mickey Wade</i>	369
Magnetic Confinement Fusion Concepts/Configurations <i>Ricardo MO Galvão and Gustavo P Canal</i>	383
Magnetic Confinement Fusion—Plasma Theory: Kinetic and Fluid Analysis <i>Yanick Sarazin</i>	404
Magnetic Confinement Fusion—Plasma Theory: Transport and Confinement <i>Frank Jenko</i>	419
Magnetic-Confinement Fusion—Plasma Theory: Tokamak Magnetohydrodynamic Equilibrium and Stability <i>Lang L Lao, YQ Liu, and Alan D Turnbull</i>	431
Magnetic Confinement Fusion—Plasma Theory: Energetic Particle Physics <i>NN Gorelenkov and SE Sharapov</i>	459
Magnetic Confinement Fusion—Plasma Theory: Heating and Current Drive <i>RJ Dumont</i>	479
Magnetic Confinement Fusion—Experimental Physics: Tokamak <i>Hartmut Zohm</i>	493
Magnetic Confinement Fusion—Experimental Physics: Stellarators <i>Hiroshi Yamada</i>	505
Magnetic Confinement Fusion—Experimental Physics: Reversed Field Pinches <i>M Zuin</i>	524
Magnetic Confinement Fusion—Technology: Fusion Core <i>Gianfranco Federici, Christian Bachmann, Valentina Corato, Samuel Jimenez, and Jeong-Ha You</i>	554
Magnetic Confinement Fusion Technology: “Plasma Engineering” <i>Takashi Inoue, Hiroyuki Tobari, Koji Takahashi, So Maruyama, Ryota Imazawa, and Kenichi Kurihara</i>	576
Fusion—Reactor Materials <i>A Litnovsky, I Duran, JW Coenen, Yu Gasparyan, MR Gilbert, E Hollmann, Ch Linsmeier, S Nogami, CH Skinner, and S Zinkle</i>	594
Magnetic Confinement Fusion—Reactor Blanket Technologies <i>Lorenzo Virgilio Boccaccini and Christian Day</i>	620
Magnetic Confinement Fusion—Development Facilities <i>AJH Donné, G Federici, A Ibarra, J Menard, and F Warmer</i>	635
Magnetic Confinement Fusion—Power Plant Concepts <i>David J Campbell</i>	655
Inertial Confinement Fusion – Physics Principles <i>Stefano Atzeni</i>	674
Inertial Confinement Fusion – Key Elements of Plasma Physics <i>Vladimir T Tikhonchuk</i>	686
Inertial Confinement Fusion—Experimental Physics: Laser Drive <i>Sean P Regan and E Michael Campbell</i>	713
Inertial Confinement Fusion—Experimental Physics: Heavy Ion Beam Drive <i>Peter A Seidl</i>	724

Inertial Confinement Fusion - Experimental Physics: Z-Pinch and Magnetized Liner Inertial Fusion <i>Matthew R Gomez, Mary Ann Sweeney, David J Ampleford, Stephen A Slutz, Gregory A Rochau, and Daniel B Sinars</i>	739
Overview of IFE Key Power Plant Technologies <i>E Michael Campbell, Jose Manuel Perlado, Javier Sanz Gozola, Susana Reyes, and Michael Tobin</i>	751
Inertial Confinement Fusion—Major Facilities <i>SM Finnegan</i>	795
Inertial Confinement Fusion Power Plants <i>Mike Dunne, Tom Anklam, and Wayne Meier</i>	807
Fusion—Safety and Environmental Considerations <i>Neill P Taylor</i>	822

VOLUME 4

Research Reactors

An Introduction to Research Reactors <i>D Sean O’Kelly</i>	1
Applications of Research Reactors <i>Nuno Pessoa Barradas</i>	8
Historical Survey of Test Reactor Programs at INL Over 70 Years <i>Harold F McFarlane</i>	26
Historical Survey of Fast Test Reactors <i>George R Imel</i>	39
The Transient Reactor Test (TREAT) Facility at the Idaho National Laboratory <i>Daniel Wachs, Nicolas Woolstenhulme, Colby Jensen, and James Parry</i>	47
The Advanced Test Reactor <i>D Sean O’Kelly</i>	56
High Flux Isotope Reactor (HFIR) <i>David Chandler and Christopher D Bryan</i>	64
The National Bureau of Standards Reactor at the NIST Center for Neutron Research <i>Thomas Newton, Daniel Flynn, and Robert Williams</i>	74
The Annular Core Research Reactor (ACRR) Description and Capabilities <i>Edward J Parma, Michael W Gregson, R David Clovis, Lance Lippert, and Lonnie E Martin</i>	82
MIR.M1 (100 MW) <i>Nikolay V Arkhangelskiy</i>	90
The BR2 Reactor: Short History, Characteristics and Utilization <i>Steven Van Dyck</i>	96
The Jules Horowitz Reactor <i>Gilles Bignan</i>	105
FRM II (20 MW Germany) <i>Heiko Gerstenberg and Winfried Petry</i>	113

MARIA Research Reactor <i>Bartłomiej Piwowski, Michał Gryziński, Rafał Prokopowicz, Anna Talarowska, Maciej Lipka, Emilia Wilińska, and Gawel Madejowski</i>	124
HANARO <i>Sooyoul Oh</i>	132
Dhruva—A 100 MWth Indian Research Reactor <i>Prabhakar V Varde, CG Karhadkar, and Tej Singh</i>	138
The OPAL Research Reactor <i>David Vittorio and Mark Summerfield</i>	147
University of Missouri Research Reactor <i>Leslie P Foyto</i>	155
MIT Research Reactor (MITR-II) <i>Lin-wen Hu</i>	164
North Carolina State University PULSTAR Reactor <i>Ayman I Hawari</i>	173
TRIGA [®] Reactors: A Unique Approach in Research Reactor Fuel and Design <i>Steve Reese</i>	182
Accelerator Driven Subcritical Systems <i>Hamid Ait Abderrahim, Didier De Bruyn, Gert Van den Eynde, and Rafaël Fernandez</i>	191
Research Reactor Conversion to Low Enriched Uranium (LEU) Fuel <i>John G Stevens</i>	203
Medical, Industrial and Agricultural Applications of Nuclear Technology	
Harnessing Nuclear Radiation <i>Alan E Waltar</i>	210
Medicine: Sterilization <i>Vikram Kalia and Deepa Joseph</i>	224

Glossary

CHP Combined heat and power.

GHG Greenhouse gas, i.e., gases in the Earth's atmosphere that trap heat, such as carbon dioxide, methane, nitrous oxide, and fluorinated gases.

HTGR High temperature gas reactor.

Hybrid production plant A combination of two power generation or industrial plants that share one or more energy sources or material inputs and produce variable amounts of energy products to optimize revenue or to meet other time varying objectives.

Integrated energy system (IES) An integrated energy system, including hybrid production plants, is connected by physical or cyber connections and operated in a manner that optimizes any or all of the following objectives: system flexibility and efficiency, revenue, resilience, security, resource stewardship, and environmental sustainability. May include two or more collocated or jointly operated subsystems of energy generation, energy storage, or other energy technologies.

LWR Light water reactor.

MSR Molten salt reactor.

Net demand Remaining demand that must be met by conventional dispatchable generation sources after variable generation is subtracted from the total electricity demand.

SFR Sodium fast reactor.

VHTR Very high temperature reactor (gas-cooled).

Nuclear power reactors provide highly reliable, dispatchable energy generation that can support a wide array of energy demands without emission of greenhouse gases. Based on 2018 data, nuclear power plants provide 18% of total energy generation globally and are the largest contributor to low-emissions electricity production in advanced economies ([International Energy Agency, 2019](#)). However, nuclear energy is poised to also provide low-emissions energy generation to support other energy demands beyond the electric grid.

Motivation

New solutions for energy generation, distribution, and utilization are emerging as the world demands a reduced environmental impact—namely, reduced CO₂ and greenhouse gas emissions—while retaining reliability, resilience, and affordability in meeting energy demands ([Arent et al., 2020](#)). These demands span the electricity, industrial, and transportation sectors, and goals for reduced emissions are being reflected in many regional, national, and organizational efforts ([Benahmed et al., 2020](#)). Meeting these goals requires leveraging all clean energy sources available, and it requires that we look to how these sources can be utilized in meeting more than just electricity demand.

In the United States, approximately 34% of CO₂ emissions are attributed to energy generated to support the electricity sector, but an additional 36% of emissions result from transportation and 19% result from industrial processes; the remainder of CO₂ emissions are attributed to residential and commercial use of natural gas and, to a small extent, petroleum resources ([Lawrence Livermore National Laboratory, 2018](#)). Many efforts to decarbonize focus on the electricity sector and look for opportunities to

electrify transportation and industrial processes. However, not all of these processes can or should be electrified. The heat demand across all energy sectors far exceeds electricity use—83% of energy is used in the form of heat, while only 17% is used in the form of electricity. In the industrial sector, as much as 88% of the energy used is heat ([Lawrence Livermore National Laboratory, 2019](#)). Hence, making significant progress toward emissions reduction must necessarily entail the increased utilization of non-emitting or low-emission thermal energy sources, such as nuclear energy, beyond the electricity sector.

Overview of nonelectric applications

Historically, nuclear power plants have primarily focused on the conversion of nuclear-generated thermal energy to electricity to support baseload demands, relying on other generators that can be rapidly ramped to meet peak electricity demand. Although some regions have long demanded flexible output from nuclear plants (e.g., France) due to the relatively large fraction of electricity demand met by nuclear energy, such a flexible operation of traditionally “baseload” plants is becoming more necessary and prevalent as more variable energy sources are added to the grid around the world ([Cox and Bragg-Sitton, 2020](#)).

In 2016, the US Department of Energy national laboratories for nuclear energy (i.e., Idaho National Laboratory) and renewable energy (i.e., National Renewable Energy Laboratory) partnered to complete a study to characterize how emissions could be reduced across the industrial sector via the use of non-emitting thermal energy generation sources, such as nuclear, concentrated solar, and geothermal ([McMillan et al., 2016](#)). Using data from the US Environmental Protection Agency Greenhouse Gas (GHG) Reporting Program, the most significant CO₂ emitters were identified across US industry, comprising 960 facilities across 14 industry sectors in 2014 and representing 25% of industrial GHG emissions for the United States in that year (5% of total US emissions). Typical processes in each of these target industries were defined, and material and energy flows were identified, in order to assess the potential to replace highly emitting resources with zero or low-emission resources. Overall, the study found that nuclear energy technologies, specifically small modular reactors, are expected to be well-matched to the scale of the demand of oil refineries, pulp and paper manufacturing, methanol, and fertilizer plants, among others. Heat recuperation and temperature augmentation were identified as important aspects of thermal energy management within these system designs, particularly for lower temperature thermal generators, and the incorporation of thermal energy storage may support matching clean energy delivery with thermal load schedules, particularly for intermittent or batch plant operations. The latter is also reflected in a recent study on the role of thermal storage in maximizing use of non-emitting energy sources across a variety of applications ([Forsberg and Bragg-Sitton, 2020](#)).

Nuclear energy generated via fission can be directed to meet a number of energy demands in a variety of configurations. These may include configurations such as:

- Electricity production only, via power conversion system (single-input, single-output system), to meet grid demand or to directly support electricity-driven processes
- Heat applications only, such that no power conversion system would be required (single-input, single-output system)
- Cogeneration, producing both heat and electricity (single-input, multioutput system)
- “Integrated” or “hybrid” energy systems, combining nuclear energy generation with other generators (multi-input, multioutput system).

The *Integrated Energy System: 2020 Roadmap* defines integrated energy systems (IES) as such ([Bragg-Sitton et al., 2020a,b,c](#)):

IES are cooperatively-controlled systems that dynamically apportion thermal and/or electrical energy to provide responsive generation to the power grid. They are composed of multiple subsystems, which may or may not be geographically co-located, including a thermal energy generation source (e.g., nuclear), a turbine that converts thermal energy to electricity, additional electricity generation source(s) (e.g., renewable generation, either directly integrated with the nuclear plant or present in the grid balancing area), and one or more industrial processes that utilize heat and/or electricity from the energy sources to produce a commodity-scale product.

The non-grid applications of nuclear energy described in this section may be implemented via one or more of these configuration options, as determined by the specific implementation scenario.

The role of energy storage

Energy storage (e.g., thermal, chemical, mechanical, hydro, electrical) may be coupled with a nuclear generator to support integration with various energy users ([Forsberg, 2021](#)). Incorporation of energy storage components may attenuate the dynamics imposed by one of the connected subsystems, or it may allow energy delivery to coupled energy users at a later time. Electrical storage options primarily focus on batteries, which are increasing in prevalence to support renewable generators. Thermal storage options include both liquid (e.g., molten salt) and solid (e.g., firebrick) forms. Stored heat may be used directly in the coupled industrial process, or it could be used to generate steam that will be fed to the steam turbine. Electrical energy may also be stored in the form of heat (via electric resistance heaters) for conversion back to electricity when it is needed to support thermally driven processes. Chemical energy storage may include the production of intermediate products, such as hydrogen, which can later be combusted or used for the production of electricity. Note that the specific need for and potential benefits of energy storage may differ for each combined heat and power (CHP) or IES architecture.

District heating

One application of thermal energy from a nuclear plant is the direct use of relatively low-temperature heat in district heating loops, as discussed in more detail by [Schweikert and Deinert \(2021\)](#). District heating describes the use of a network to distribute heat from a centralized location through insulated energy transport pathways to support residential and commercial heating requirements. Heat to support such a network is often obtained from a cogeneration plant via the combustion of fossil fuel or biomass, or heat may be derived from geothermal sources, heat pumps, or centralized solar heating. Nuclear-driven district heating systems often operate using waste heat rejected from the secondary side of the nuclear plant in the power conversion process. District heating is most often applied in climate zones having long, cold winter seasons, with heat being provided in the form of hot water or steam at low pressure and at temperatures below 200 °C ([International Atomic Energy Agency, 2019a](#)).

Most nuclear district heating applications are located in Eastern Europe and the Russian Federation, with China bringing a nuclear district heating plant online in 2020 ([World Nuclear News, 2020](#)). As summarized in ([International Atomic Energy Agency, 2019a](#)), 43 reactors around the world have supported district heating as of 2019, providing an average energy withdrawal of less than 5%. Hence, in all of these applications, the primary output has still been electrical power. Heat transport distance is generally limited due to inefficiencies over long distances, with steam transport often limited to ~5 km ([International Atomic Energy Agency, 2012](#)). The most recent nuclear district heating system to come online at China's Haiyang nuclear power plant uses steam from two AP1000 light-water reactor (LWR) reactors, extracted from the secondary side and directed to a multistage heat exchanger to transfer offsite, to heat water for municipal heating. Haiyang plans to heat up to 30 million square meters using the two AP1000 units, potentially providing heating for up to 200 million square meters of buildings and housing within a radius as large as 100 km with the addition of more nuclear units at the site ([International Atomic Energy Agency, 2019a](#)).

Coupling of industrial processes

When an industrial process is coupled within a nuclear cogeneration or integrated energy system, the process receives heat or power from the nuclear reactor(s), the turbine, and other integrated energy sources (e.g., renewable energy source) as needed, or as the power or heat is available. The connected energy user would produce commodity products that provide another income stream to the nuclear generator. Key products may include potable water, hydrogen, synfuels, and chemicals, among others, produced using the heat or electricity.

In a cogeneration or integrated system, when heat from the nuclear reactor is diverted to electricity production, the heat delivered to the industrial process can be reduced, or the heat necessary to operate the process can be derived from another source (e.g., natural-gas-fired unit or stored energy, such as thermal energy storage or stored hydrogen, if the aim is to reduce carbon emissions). When the nuclear-generated heat or electricity replaces fossil-based resources, such a solution can dramatically reduce environmental emissions associated with the industrial process.

Another option is for the nuclear generator to be deployed in a traditional CHP system that may not support the electricity grid as a primary user. In this case, the nuclear reactor would be owned by a given industry or complex of industries to provide a dedicated source of heat and power to the industrial processes. If necessary, the system may occasionally direct electricity to the grid under a contract to provide a reserve capacity when needed. This option is similar to the manner in which many CHP units operate today. The evolution of the public electricity grid to include more variable generation sources may require the more frequent support of grid peak demand, such that industrial CHP units may be contracted to provide spinning or non-spinning reserve capacity or even power modulation to help regulate the grid while also supporting industrial processes.

Most industrial processes demand a constant energy input to support constant operation to ensure economic profitability and optimal performance, although some processes could be designed to operate flexibly if sufficient economic incentives are offered. The ability to ramp many industrial processes is limited due to performance reduction, impacts on economic profitability, and wear or damage on the process equipment. These implications must be considered in process development and design of the coupled CHP or IES.

Recent modeling and simulation efforts have effectively demonstrated the value of flexible operation of LWR plants ([Boardman et al., 2019](#); [Epiney et al., 2019](#); [Frick et al., 2019](#); [Cox and Bragg-Sitton, 2020](#)) to improve economic performance while supporting the grid demand. Flexible LWR operation (i.e., flexible electrical output to the grid while maintaining constant reactor thermal power) allows these plants to support both the industrial and transportation sectors by providing low-cost, low-emissions energy. Potential nuclear plant connections to large US industries are shown in [Fig. 1](#), where the nuclear power plant is the primary source of energy for producing fuels, ammonia, steel, polymers, and hydrogen. In the illustrated system configuration, the production of hydrogen as a process intermediate provides a key energy currency that can effectively incorporate nuclear energy into existing or new industrial applications. There are several processes for producing hydrogen without the CO₂ emissions that accompany the predominant steam methane reforming process, as described by [Suppiah \(2021\)](#) and [Boardman et al. \(2021\)](#).

Introduction of advanced, higher temperature reactors to CHP or IES offers the potential to extract heat at higher temperature (e.g., 500–750 °C) to more efficiently support industrial processes, meeting both their thermal and electricity demands while maintaining environmental stewardship ([Sabharwall et al., 2012](#); [Futterer 2021](#); [Reitsma 2021](#)). Although most of the global research and development (R&D) for advanced reactors focuses on temperatures below 750 °C, note that some R&D associated with the development of very high-temperature reactors (VHTRs) still continues. VHTR research seeks to achieve operating temperatures as high as 900 °C, but these systems require additional development due to significant materials challenges ([International Atomic Energy Agency, 2019b](#)).

Fig. 1 Illustrative examples of the near-term integration of existing LWRs with various industry applications. From Bragg-Sitton SM, et al. (2020) *Integrated Energy Systems: 2020 Roadmap*. Idaho Falls: Idaho National Laboratory. <https://doi.org/10.2172/1670434>, used with permission.

High priority industrial applications

The *Integrated Energy Systems: 2020 Roadmap* issued by the US DOE Idaho National Laboratory (Bragg-Sitton et al., 2020a,b,c) breaks down energy-intensive manufacturing industry applications based on heat requirement and potential heat transfer media (Pelligrino et al., 2004), see Table 1. Specialized markets, such as pharmaceuticals, that require tight quality control and do not demand a large electrical or thermal input are not listed here.

The US manufacturing industry used about 25 exajoules (i.e., 25×10^{18} J) of delivered energy in 2014, of which approximately 20% is from electricity (with about one-third produced onsite for captive use), 40% from steam (all generated onsite), and 40% from fossil-fired combustion as a source of either direct heating, such as in a cement kiln, or indirect heating, such as in fired-heaters (Ruth et al., 2014). Combustion of fossil fuels currently provides over 90% of the primary energy required for these processes. Hydroelectrical dams that support the aluminum metal production industry and biomass refuse combustion in CHP plants are still the main source of non-fossil energy sources used by the industrial sector.

Alternately, a majority of the industrial steam and heat duty requirements to support the processes summarized in Table 1 could be directly derived from LWRs through temperature augmentation techniques or could be derived by coupling energy use processes with advanced, higher temperature reactors. Steam super-heating with a fossil fuel, chemical heat pumps, or other technologies could be used to amplify LWR steam temperatures to the necessary service temperatures of processes requiring heat in excess of 300 °C (the approximate temperature at the outlet of an LWR) with minimal GHG emission. Use of high-temperature reactors, especially gas- and molten-salt-cooled designs, would reduce the need to augment steam heating. Heat augmentation technologies

Table 1 Development needs for chemical manufacturing process heating and electrification with nuclear energy.

Type of heat duty	Process examples	Process temperature ^a (°C)	Nuclear reactor options	Heat transfer media	Process-related R&D needs
Feedstock Drying & Minerals Concentration	- Biomass - Lumber - Phosphate production - Food dehydration and cooking - Wood pulp production and paper/cardboard plants	50–175	All	Steam or hot gases; phase-change heat storage media	Heat transport networks and other thermal energy storage and delivery approaches
Sub-combustibility	- Biomass torrefaction^b - Thermal plastics forming and modeling	50–300	All		
Evaporation	Ethanol distillation	120–150	All		
Petroleum Distillation	Reboiler heating	550–600	MSR, VHTR	Superheated steam, hot gases, molten salts	Reboiler design; heat circulation systems
Biomass and Coal Pyrolysis	Indirect heating	500–650	MSR, VHTR	Hot gases, molten salts	Reactor heating concepts to support pyrolysis; heat circulation systems; heat augmentation
Combined Heat and Power	Brayton or Rankine power cycles	450–950	SFR, MSR, HTGR, VHTR	Steam or hot gases	Power cycles turbo-machinery
Hydrotreating or Hydrogenation	Fluid catalytic cracker	700–750	MSR, HTGR, VHTR	Hot gases	Reactor heat transfer design and testing
Steam Cracking	- Natural gas reforming - Olefin reforming	800–850	VHTR	Helium	Bottoming heat use (e.g., power generation); reforming process modifications
Oxidative Coupling	Benzene for styrene, etc.	800–850	VHTR	Helium	Bottoming heat use; e.g., power generation
Calcination	Lime and quick lime	800–850	VHTR	Helium	Bottoming heat use; e.g., power generation
Low-Temperature Electrochemical Process Heating	- Formic acid production - Low-temperature electrolysis	25–80	All	Hot oil, pressurized water	Low-cost heat transport manifold and heat recuperation
Intermediate Temperature Electrochemical Process Heating	- Alkane deprotonation - Aqueous CO₂ reduction - Proton-conduction solid-oxide electrolysis	500–600	MSR	Hot inert gases	Low-cost heat transport manifold and heat recuperation
High-Temperature Electrochemical Process Heating	High-Temperature Electrolysis	800–850	All	Ultra-supercritical steam; hot inert gases	

^aNote that low process temperatures can be supported by electric heating versus direct thermal integration.

^bTorrefaction is a thermal process to convert biomass into a coal-like material, which has better fuel characteristics than the original biomass.

From Bragg-Sitton SM, et al. (2020) *Integrated Energy Systems: 2020 Roadmap*. Idaho Falls: Idaho National Laboratory. <https://doi.org/10.2172/1670434>, used with permission.

that could enable utilization of lower temperature reactor technologies (e.g., LWRs) for high-temperature process applications may include resistive heating, high-temperature heat pumps (i.e., having a heat sink temperature > 90 °C, as defined in Herring, 2021), or chemical heat pumps. While a standard heat pump utilizes a vapor-compression refrigeration cycle to increase the temperature of the working fluid, chemical heat pumps utilize reversible chemical reactions for energy storage (endothermic reaction) and release (exothermic reaction) to increase temperature of the working fluid (Sabharwall et al., 2013).

Interface technologies

Integration of non-grid processes with a nuclear plant may be accomplished via direct thermal integration or electrical integration, each of which pose different technical and regulatory challenges.

Electrically integrated processes

Some non-grid energy use applications that require electrical energy input may benefit from power transactions behind the grid (e.g., direct electrical integration with the nuclear plant, outside of the nuclear island but behind the interconnection to the grid). For example, industrial energy users often include batch operations that can be coordinated to smooth the overall power use profile, thereby optimizing the operating efficiency of the nuclear plant. An industrial complex can be designed in a manner

that shares the capital costs across different subsystems, and the complex may also engage in power transactions with the grid to meet peak demands. These arrangements currently are very difficult to negotiate in a regulated electricity market, while they are more common in deregulated markets.

The electrical power system within a nuclear plant supplies power to all systems in the plant on both the primary and secondary side, including safety systems. Hence, the plant's electric power system design must be engineered with every possible contingency in mind. Direct integration with the industrial users will require modifications to a typical switchyard to account for power delivery to the coupled power user (e.g., hydrogen production, desalination) and other unit operations that divert more than 10% of the total capacity of a nuclear reactor in a hybrid system. Power system modeling tools should be employed to support the design of the power distribution and transmission systems to ensure that they retain realistic behavior and to reduce the risk of tripping the nuclear reactor due to interruptions in the power system. Additionally, the incorporation of behind-the-grid electricity users requires the introduction of a new order of communications with the grid operator, which needs to enable the operators to command the nuclear-industry systems functioning behind the grid to effectively use the system for grid services.

Thermally integrated processes

Heat exchangers provide a means to transfer heat to or from fluids of differing pressures, temperatures, and compositions. This is one of the key components needed to thermally connect IES subsystems. As described in Bragg-Sitton et al. (2016), heat exchangers must provide a pressure and chemical boundary and should demonstrate both a high performance efficiency and reliability under dynamic conditions. Advanced heat exchanger design and manufacturing capabilities, such as diffusion bonding or additive manufacturing, may be needed to meet these requirements in a satisfactory manner. Candidate advanced heat exchanger designs should be developed with the support of multiphysics computational modeling methods. It is expected that heat exchanger designs will vary depending on imposed requirements of the coupled subsystems.

Tightly coupled, thermally integrated systems may require a tertiary loop to deliver heat or power for industrial processes. Such a design is not standard to nuclear systems, but this integration approach can provide the isolation of the nonnuclear systems from the nuclear system, ensuring that the coupled process is isolated from potential radioactive contamination under all normal and off-normal operating scenarios. Within integrated energy parks, tertiary loops must be viable for all systems directly attached to it from both a hazards and an operational perspective. These requirements could demand the selection of multiple working fluids depending on the systems being integrated, potentially requiring a range of step-down fluids in the tertiary loops. For example, a gas turbine that operates at 600 °C will require a different tertiary loop fluid than a nuclear power plant that operates at 300 °C. The selected industrial application and its corresponding temperature requirement will also affect the working fluid selection for tertiary loops. Understanding potential fluid interactions between loops will be a vital part of the selection process as well.

Limited research is publicly available on the mass transport of thermal energy via these tertiary loops for medium temperature applications applicable to many IES configurations. Research is being conducted for various medium temperature intermediate loops through several research projects (Stoots et al., 2018; Frick et al., 2020). However, increased investment is needed to support research and development into the possible fluid interactions between loops, loop control systems, amount of holdup required, and siting relative to different thermal generators.

Topics covered in section 8

This section covers a suite of potential applications of nuclear energy to support non-grid energy demands. While the topics covered here are not intended to be comprehensive, they do cover many of the options currently being pursued by research organizations, reactor developers, and industry around the world.

Chapter Summary:

District Heating and Nuclear Power	A. Schweikert and M. Deinert
Process Heat for the Chemical Industry	R. Boardman, M. McKellar, B. Dold, A. Foss, H. Bryan
Nuclear Driven Water Desalination	A. Epiney, K. Frick, C. Rabiti, J. Brown, S. Bragg-Sitton
Coupling Heat Storage to Baseload Nuclear Reactors for Heat, Electricity, and Hydrogen	C. Forsberg
Marine Propulsion	A. Anand and J.S. Herring
Heat Pumps	J.S. Herring
Nuclear-supported Electrification of the Transportation Sector	A. Elgowainy
Thermochemical Hydrogen Production	S. Suppiah
High Temperature Steam Electrolysis	R. Boardman, D. Wendt, C. Rabiti
Synthetic Hydrocarbon Fuels from H ₂ and Captured CO ₂	J. Holladay, L. Snowden-Swan, S. Li, J. Askander, J. Jenks, S. Phillips, L.T. Knighton, D. Wendt
Industrial Processes for Grid Stabilization	F. Bienvenu
Ammonia Synthesis Using Nuclear-produced Hydrogen	R. Boardman
Hydrogen-based Flash Ironmaking Technology (HyFIT): A Novel Green Ironmaking Technology with Low Energy Consumption	H.Y. Sohn
Calcination	N. Haneklaus

Overview

District heating systems distribute thermal energy from a centralized source to residential and commercial buildings through a network of pipes to provide space heating and/or hot water. The piping networks convey steam, hot water, or other mixtures and can be located above or below ground. They are often insulated to reduce heat losses during transmission. Most modern systems (“third generation”) have piping networks underground for safety reasons and to reduce thermal losses during conveyance (Mazhar et al., 2018). District heating systems can vary in size and serve a small industrial complex or small residential neighborhood as well as larger, urban systems (Lund et al., 2014; Mazhar et al., 2018). These systems are best suited for locations with dense buildings where losses from longer piping networks can be minimized. Historically, district heating was developed in regions with harsh winter climates including Scandinavia, Eastern Europe and Russia. However, they are increasingly being upgraded and reconsidered globally due to the potential to generate secure, low-emissions heat products when powered by clean and renewable sources (Joint Institute for Strategic Energy Analysis (JISEA), 2020; Lund et al., 2014; Mazhar et al., 2018; Zhivov et al., 2006). In many regions, district heating systems are widely utilized and provide safe, efficient, low-cost heat (World Nuclear News, 2020; Zhivov et al., 2006).

The heat sources for district heating can be dedicated to the purpose, although waste heat from power generation is often used. Cogeneration facilities that are designed to combine heat and power (CHP) production for specific campuses or industrial complexes are an example. When waste heat is used, district heating has the added benefit of reducing carbon emissions that would come from burning conventional fuels to provide heating as well as for reducing thermal pollution from waste heat (discharge of heat to the environment) (Burkhard and Basler, 1976). For nuclear power, district heating can be one of several cogeneration products, alongside desalination, hydrogen production, industrial heat and other products designed to increase the thermal efficiency and revenue of the power plant. The benefits of cogenerating district heating with nuclear power include increased revenue from otherwise unused waste heat, reduced operational environmental impacts from cooling water discharge into lakes or rivers, and increased energy security (International Atomic Energy Agency, 2002; Joint Institute for Strategic Energy Analysis (JISEA), 2020). The most significant challenges related to district heating with nuclear power include the distance between generation source and end use and considerations about the reliability of supply from single-generator facilities (International Atomic Energy Agency, 2002). In this context, the potential for small and micro modular reactors (SMRs) may provide new avenues for clean, reliable and sustainable CHP solutions in many regions of the world (Joint Institute for Strategic Energy Analysis (JISEA), 2020; Värri and Syri, 2019).

History

The earliest implementation of a district heating system is attributed to Lyon, France, where geothermal sources were harnessed to provide hot water to homes (Mazhar et al., 2018). Modern district heating systems have evolved over approximately 150 years, with the earliest “first generation” systems developing in the 1880s in the United States and Europe. These systems conveyed high temperature (> 150 °C) steam through concrete duct transmission systems to dense urban centers, including New York City (United States) and Paris (France). High rates of heat loss and severe accident potential motivated further development (Mazhar et al., 2018). Second generation systems emerged in the 1930s and were characterized by lower (but still considerable) temperatures,

typically ≥ 100 °C, and the introduction of pressurized water as the heat carrier (Lund et al., 2014). Much of the development of district heating systems in the former Soviet Union consisted of second-generation technology, which suffered from high heat losses due to a lack of demand control (Lund et al., 2014).

Third generation systems, sometimes referred to as “Scandinavian” systems, emerged in the 1970s (Lund et al., 2014). Pressurized water was still used for thermal transport, but with temperatures ranging around, and often below, 100 °C. This allowed for less costly piping materials, increased insulation opportunities and potentially reduced risk from damages or leakages of pipes (Zhivov et al., 2006). Third generation systems also included innovations such as prefabricated, pre-insulated pipes made of steel and other materials and buried underground in trenches or tunnels (Mazhar et al., 2018). This included underground pipes insulated with polyurethane foam which could be used with lower temperature water transport (< 140 °C) to reduce thermal losses and lower maintenance requirements (Zhivov et al., 2006). Third generation technology is the current standard for new systems (including those in China, Korea, Europe, the United States and Canada) as well as the target when upgrading older systems (especially prevalent in Central and Eastern Europe and Russia). An overall trend of “generational” development is the lowering of transmission temperatures and upgrades in piping fabrication and materials to reduce costs and heat losses. A summary of generational developments and key attributes can be found in Table 1, summarized from Lund et al. (2014) and Mazhar et al. (2018).

System components

District heating systems can be broken into three main components: generation, transmission, and distribution, Fig. 1. The generation system is comprised of one or more heat producing facilities, with water as the primary heat transfer medium, although some systems use steam or other products. The benefits of using water (when compared to steam) include ease of control, reduced maintenance costs, increased safety, less prone to leakage, and longer piping life (Zhivov et al., 2006). The most common type of generation system is CHP, which can be implemented with conventional fuels but also served by municipal waste combustion, geothermal sources, solar thermal heat, or nuclear power (Mazhar et al., 2018). Attempts have been made to rank generation options for district heating based on economics, environment and energy use to identify the optimal system based on multi-factor considerations. CHP is generally seen as the most optimal choice. However, it is also noted that the optimal solution can vary if only one parameter (e.g., focus exclusively on only the environmental, economics, or energy use parameter) is considered above the others (Wei et al., 2010).

Table 1 Summary of district heating system evolution and key attributes.

	<i>1st Generation</i>	<i>2nd Generation</i>	<i>3rd Generation</i>	<i>4th Generation</i>
Time Period	1880–1930	1930–1980	1980–present	<i>future</i>
Primary region deployed	USA, Europe	Soviet Union	Scandinavia ^a	
Heat Carrier	Steam	Pressurized hot water	Pressurized hot water	Lower-temperature water
Temperature of heat carrier ^b	> 150 °C	100–120 °C	70–120 °C	40–60 °C
Pipes	In situ (concrete duct) steel pipes	In situ (concrete duct) steel pipes	Pre-insulated steel pipes, underground	Pre-insulated flexible pipes
Circulation systems	Steam pressure	Central pumps	Central pumps	Central and decentralized pumps
Substations/Heat Exchanger	None	Tube-and-shell	Heat exchangers with or without plates	<i>not yet determined</i>
Radiators	High-temperature radiators (> 90 °C), steam or water	High-temperature radiator (90 °C) using DH water	Medium-temperature (70 °C) radiators using DH water	Floor heating, lower-temperature (50 °C) radiators
Infrastructure Planning	Accounting for different DH infrastructures	Developing and expanding DH, focus on efficient use of CHP	Identifying and implementing infrastructure, largely fossil-based system	Identifying and implementing fossil-free energy system applications
Primary motivation	Comfort in buildings, reduced risk	Fuel savings, reduced costs	Security of supply, safety	Sustainable energy system, environmental impacts

^a“DH”, district heating; “CHP”, combined heat and power; “°C”, degrees Celsius.

^bLargely developed in Scandinavia, but deployed to upgrade older systems in Eastern Europe and former USSR regions, new systems in China, United States, Europe, Korea and Canada.

Fig. 1 District heating and electricity cogeneration example.

The transmission network in district heating systems consists of the main transmission lines that connect the generation source to the distribution networks that bring heat to the end users. Costs for transmission networks can be significant and vary widely by geography within (rural, urban) and between countries (Mazhar et al., 2018). Other factors such as pipe diameter, length, material, insulation thickness, and burial depth are also important, and network costs can vary by an order of magnitude or more as a result (Zhivov et al., 2006). Transmission networks are typically made of insulated steel buried in trenches or tunnels, with a lifetime of 20–50 years. They can operate at varying temperatures and pressures, with higher temperature and pressure pipes (16–25 bars) made of steel, copper or aluminum. Lower temperature and pressure pipes can be made of different materials including plastic, potentially lowering costs for construction and operations (Mazhar et al., 2018; Zhivov et al., 2006). Transmission networks also include pumps, control equipment and sensors. Heat losses during transmission are a major source of loss, ranging from 5–20% or higher, especially dependent on insulation of pipes and distance traveled between source and end use.

The distribution network is the third component of a district heating system and is the part of the system directly connected to end users, Fig. 2. There are two types of distribution systems: direct and indirect. Direct systems do not have a decoupling between the transmission line from the heat source and the distribution. This reduces losses and costs associated with heat exchangers. However, direct systems can result in higher costs for control and pressure, and leaks or contamination from within buildings can directly affect the entire district heating system (Mazhar et al., 2018). Indirect systems reduce these problems. With indirect systems, a heat exchanger at a substation is used to decouple fluid in the transmission from the distribution piping networks that take heat to end users (Mazhar et al., 2018). This allows the transmission and distribution systems to operate at different

Fig. 2 Simple schematic of combined heat and power (CHP) system including direct and indirect distribution networks.

pressures and helps to isolate any potential sources of contamination. Heat exchangers are typically made of stainless steel, with the most common types being plate heat or shell-and-tube. Shell-and-tube systems allow for better heat transfer but are larger in physical size and less dynamic in load shifting. Heat meters account for the heat use at each end-use destination. This is a key area for emerging research and application of “integrated” and “smart” grids to reduce energy demand and consumption (Lund et al., 2014; Mazhar et al., 2018).
